The process by which species evolve can be illuminated by investigating barriers that limit gene 16 17 flow between taxa. Recent radiations, such as Heliconius butterflies, offer the opportunity to 18 compare isolation between pairs of taxa at different stages of ecological, geographic and phylogenetic divergence. We carry out a comparative analysis of existing and novel data in 19 20 order to quantify the strength and direction of isolating barriers within a well-studied clade of 21 Heliconius. Our results highlight that increased divergence is associated with the accumulation 22 of stronger and more numerous barriers to gene flow. Wing pattern is both under natural 23 selection for Müllerian mimicry and involved in mate choice, and therefore underlies several 24 isolating barriers. However, pairs which share a similar wing pattern also display strong reproductive isolation mediated by traits other than wing pattern. This suggests that, while wing 25 26 pattern is a key factor for early stages of divergence, it may become facultative at later stages 27 of divergence. Additional factors including habitat partitioning, hybrid sterility and chemically-28 mediated mate choice are associated with complete speciation. Therefore, although most 29 previous work has emphasised the role of wing pattern, our comparative results highlight that 30 speciation is a multidimensional process, whose completion is stabilized by many factors.

### 32 Introduction

33 Studies of speciation have long contrasted allopatric and sympatric speciation, speciation 34 through sexual versus natural selection, and ecological versus non-ecological speciation. 35 However, these contrasts do not always reflect the diversity of processes involved in divergence 36 and the challenge is to reach an integrated understanding of speciation [1-3]. Species divergence 37 involves multiple different traits and processes that can lead to reproductive isolation [4]. These 38 include adaptation to local environmental conditions, pre-mating isolation, and post-mating 39 effects that reduce the fitness of hybrids. To untangle the evolutionary processes at play, it is 40 useful to quantify the relative importance of the factors reducing gene flow between diverging 41 populations [5].

42

43 Speciation is a continuous process and we can typically only observe the results of divergence 44 at a specific stage, not the process in its entirety. For instance, incompatibilities between extant 45 species may not reveal the ecological and evolutionary forces initially causing divergence [6]. Conversely, ecotypes or subspecies at early divergence may shed light on factors favouring 46 47 early divergence but speciation is not a necessary outcome [3,7] and the challenge of speciation 48 with gene flow might not be its initiation but its progression and completion [8]. In that context, 49 a useful way to study speciation as a continuous process is to compare multiple pairs of incipient 50 or closely-related species which vary in their extent of divergence, possibly depicting stages 51 along the so-called speciation continuum. While keeping in mind that those pairs of taxa may 52 or may not become pairs of species, and that there may be more than one trajectory of 53 divergence, studying those pairs within the speciation continuum framework is informative of the mechanisms allowing them to involved in reaching and maintaining different levels of 54 55 divergence. [7-11].

57 With a large diversity of recently diverged species and sub-species, the radiation of Heliconius 58 butterflies is an excellent system for studying speciation with gene flow [12]. Within 59 Heliconius, two sister-clades, melpomene-clade and cydno-clade, each contain a large number 60 of local representatives across the Neotropics (Fig.1). They provide replicate pairs of taxa distributed along a continuum of divergence, notably spanning the "grey zone of speciation" 61 62 [11], providing an opportunity to assess the factors shaping reproductive isolation along the speciation process. Heliconius melpomene is considered a single taxonomic species but 63 64 comprises populations with significant genetic differentiation between western and eastern populations on either side of the Andes [13,14]. The cydno-clade includes four taxonomic 65 66 species, H. cydno, H. pachinus, H. timareta, H. heurippa. Across their range, representatives 67 of the cydno-clade are typically broadly sympatric with H. melpomene and hybridize at low 68 frequency [15-17], offering an opportunity to study both pre- and post-mating factors of 69 reproductive isolation, even between clades that diverged about 2 million years ago [13].

70

71

Research on speciation in *Heliconius* butterflies has put emphasis on behavioural pre-mating isolation, found to be strong in most pairs of taxa [18-21]. However, other factors affecting differentiation such as microhabitat partitioning [22], hybrid fertility [23,24], hybrid survival in the wild [25] and hybrid mating success [26] have also received some attention. Here, to provide an extensive comparison across the whole clade, we conduct a joint re-analysis of those published data with new data and quantify the contribution to reproductive isolation of each isolating component.

79

Most studies focus on pairs of species diverging in wing colour pattern. Wing pattern has been
termed a 'magic trait' causing speciation, because disruptive selection and assortative mating

82 operate directly on the same trait, wing pattern, thereby coupling two key forms of reproductive 83 isolation [18,25,27-29]. First, *Heliconius* wing patterns are warning signals under strong natural 84 selection for Müllerian mimicry [30,31]. Individuals not fitting one of the warning patterns 85 recognised by predators suffer a higher risk of predation and there is evidence for selection against immigrant and hybrid wing patterns [25,30,31]. Second, wing patterns are also involved 86 87 in mate-recognition in *Heliconius*, and males typically preferentially court females displaying their own colour pattern [18,20,26,32]. The loci controlling colour pattern appear to be tightly 88 89 linked to mate preference loci, which may help maintain the association between signal and 90 preference [19,33]. Consequently, wing pattern divergence causes reproductive isolation both through hybrid unfitness and assortative mating, and in Heliconius, speciation is indeed 91 92 frequently associated with a colour pattern shift [27,34,35].

93

94 Cases of mimicry between closely-related species were unknown in Heliconius until the 95 discovery of new cryptic subspecies of H. timareta in sympatry with its co-mimic H. 96 melpomene [17,36-38]. Less is known about the mechanisms responsible for reproductive 97 isolation between these species pairs with similar wing patterns, but this will be important in 98 understanding the role of mimicry shifts in reproductive isolation. Indeed, wing-pattern 99 similarity may be predicted to increase the frequency of heterospecific mating, as well as 100 increase the survival of hybrid adults, and so may weaken both pre-mating and post-mating 101 isolation.

102

In this study, we investigate the mechanisms involved in the build-up of reproductive isolation, by means of a large-scale, comparative analysis on this clade of *Heliconius* butterflies. We combine new data with data collected from the existing literature. The numerous studies of *Heliconius* taxon-pairs at various levels of divergence allow us to evaluate the relative 107 importance of different barriers to gene flow and their emergence along a continuum of 108 divergence. We have applied a unified framework for the quantification of isolating barriers 109 that facilitates these comparisons [5]. By contrasting co-mimetic *vs*. non-mimetic pairs of 110 species, we also specifically address the importance of wing-pattern as a 'magic trait' for 111 reproductive isolation in *Heliconius*.

112

113 Methods

# 114 Species studied and the continuum of divergence

We considered published data from all representatives of the cydno-clade, *H. cydno, H. pachinus, H. timareta, H. heurippa* and from the two *H. melpomene* lineages (Fig.1; Table.S1).
New data is provided for the pair of co-mimics *H. t. thelxinoe/H. m. amaryllis, H. t. florencia/H. m. malleti* and three non-mimetic pairs *H. heurippa/H. c. cordula/H. m. melpomene* in
supplementary material.

120

121 The pair of taxa examined display variable levels of genetic divergence which we here sort into 122 three broad categories. Firstly, phylogenies support a split between the cydno-clade and the 123 melpomene-clade about 1.5-2 My ago [13], so pairs of taxa involving a representative of the 124 melpomene-clade and a representative of the cydno-clade were called "pairs at high 125 divergence". Secondly, each clade comprises pairs of taxa with significant genetic divergence 126 (Table.1&S2) and consistent genetic clustering [14] and were considered at "intermediate 127 divergence". Within the cydno-clade, those pairs correspond to separate species replacing each 128 other in parapatry such as H. cydno galanthus and H. pachinus [19,39], or H. cydno cordula 129 and *H. heurippa* [24,40]. Within the melpomene-clade, allopatric subspecies of *H. melpomene* 130 belonging to the eastern and western lineage show intermediate divergence [18]. Thirdly, other 131 within-clade pairs of taxa do not exhibit significant genome-wide differentiation and were considered at "low divergence" [14,32,41]. Those correspond to sympatric forms of *H. cydno alithea* [19,32] and to parapatric races of *H. timareta* [42,43] or *H. melpomene* [20].

135 General framework: quantifying the strength of reproductive isolation (RI)

We quantified the strength of reproductive isolation (RI) for each isolating barrier following [5,44]. Briefly, the index *RI* offers a linear quantification of RI associated with the presence of a given barrier relatively to expectations in the absence of all barriers. It allows a direct link to gene flow: *RI*=1 when isolation prevents gene flow, whereas *RI*=0 if the probability that gene flow does not differ from expectations without this barrier. Confidence interval for the index can be drawn from confidence interval on the data (Table.S3).

142

143 The strength of RI provided by each pre-mating/post-mating barrier is estimated with the 144 expression:

145 
$$RI_{barrier1} = 1 - 2 \times \frac{H_1}{H_1 + C_1}$$

146 where  $H_1$  is the frequency of heterospecific mating/the fitness of hybrids and  $C_1$  the frequency 147 of conspecific mating/the fitness of pure individuals.

148

149 RI was calculated separately for both directions of crosses (AxB and BxA; female given first).

We summarize hereafter how each barrier was investigated. Detailed methods are given insupplementary material.

152

#### 154 Local co-occurrence

Although taxa may overlap in range at a broad geographic scale, encounter rates between individuals of the same taxon or across taxa may still differ. For four pairs of species collected in several locations equally distributed along a transition zone between microhabitats (Fig.S1), we use raw collection data (assuming equal collecting efforts on both species) as a proxy for natural encounter rates, and draw an estimate of the expected number of heterospecific *vs*. conspecific matings which we use to calculate reproductive isolation associated with probabilities of co-occurrence, *RI*<sub>co-cocurrence</sub>

162

### 163 Behavioural pre-mating isolating barriers

*Heliconius* males usually patrol the habitat, approach females and perform courtship characterized by intense wing flapping over the female. Females can accept or reject mating [45]. Most studies have investigated male attraction by visual cues (on models), male preference towards live females, and mating. Those three facets of mate choice were analysed separately to dissect their respective contribution to sexual isolation. Achieved mating, which reflects the multiple aspects of mate choice by both sexes leading to a mating event, was used for the whole comparison between barriers.

171

## 172 Visual cues:

In all studies, male preference for different visual cues has been estimated by presenting a group
of males with a model made with dead female wings dissected and by recording courtship
towards each model.

#### 177 Male choice

In all studies, individually-marked males were monitored for courtship during a short time
interval when presented with a heterospecific and a conspecific freshly emerged, virgin female
(live-female experiment).

181

# 182 Achieved mating

To investigate mating achievement, most studies have simulated a natural situation, either with a no-choice experiment in which a virgin female (conspecific or hetero-specific) is presented to males for 48h, or with a tetrad experiment, where four individuals, one male and one female of each species, were kept until the first mating occurred.

# 187 Post-mating isolating barriers

#### 188 F1 Hatch rate -hybrid sterility

Most studies quantified egg hatching rate in heterospecific crosses of first generation (F1) and second generation (back-crosses), which allows inferring F1 male and female fertility. Mated females were kept in individual cages with various fresh shoots of several *Passiflora* species. Eggs were collected on a regular schedule, stored individually in small plastic cups, identified and checked daily for hatching.

194

#### 195 Hybrid larval fitness

Hybrid survival was recorded only for four pairs. In all cases, larvae were raised in individual plastic containers for the first instar. Then, they were gathered by family group in a larger box and fed *ad libitum* on young shoots of *Passiflora* sp. Survival rate was calculated for each family as the proportion of larvae growing until imago.

201 Hybrid adult fitness

Survival was estimated experimentally in Panama for *H. m. rosina*, *H. c. chioneus* and their  $F_1$ hybrids, from attack rates on artificial models made with plasticine and paper wings exposed during 3 days in the wild [25]. Survival was also estimated by mark-release-resight in Ecuador on the yellow and white morphs of *H. c. alithea*, (F1 hybrids are white)[30].

206

207 Hybrid ability to mate has been investigated with no-choice experiments, live-female208 experiment or using wing models (Table.S1).

209

# 210 Results (Table.1, Fig.2)

#### 211 *Co-occurrence*

For four highly-divergent species pairs that overlap on a large portion of their range, local cooccurrence was finely quantified (Fig. S1) to estimate the probability of encounters. We found that relative differences in species frequencies contributes significantly to RI in both mimetic and non-mimetic pairs ( $RI_{co-occurrence}$ =0.48-0.91).

This heterogeneous microspatial distribution corresponds to microhabitat transition, suggesting microhabitat partitioning between taxa. For instance, *H. c. chioneus* and *H. m. rosina* feed on different pollen sources and *H. c. chioneus* occupies tall forest habitats where its co-mimic *H. sapho* is abundant, whereas *H. m. rosina* is frequent in edge habitats where *H. erato* is abundant [22]. Similarly, with increasing altitude, *H. t. thelxinoe, H. t. florencia* or *H. heurippa* progressively replace the local *H. melpomene* representative, and are also associated with closed forested habitat.

223

#### 225 Behavioural pre-mating isolating barriers (Fig.3)

226 Visual cues

227 At high divergence, isolation due to male preference based on models (visual cues only) is 228 strong for pairs with different colour patterns. It is generally higher in the direction involving 229 melpomene males (RIcolour=0.75-0.94, except for H. c. cordula/H. m. melpomene at 230  $RI_{colour}=0.28$ ) than in the other direction (cydno-clade males,  $RI_{colour}=0.35-0.5$ ). Colour 231 preference is lower between H. heurippa and H. m. melpomene than between other pairs 232 diverging in colour pattern ( $RI_{colour}=0.07/0.2$ ). This might be due to the intermediate pattern of 233 H. heurippa, which includes the red band of H. m. melpomene. In the co-mimetic pairs, males 234 do not discriminate between models, as expected given the high visual similarity of the two species. 235

236

At intermediate divergence, colour preference remains an isolating factor although its strength varies depending on the pair considered. *RI<sub>colour</sub>* reaches 0.85/0.98 between *H. c. galanthus* and *H. pachinus* but only 0.17/0.56 between *H. heurippa* and *H. c. cordula*. It is zero between the allopatric *H. m. rosina* and *H. m. melpomene*, probably because of the red forewing band shared by the two subspecies.

242

At low divergence, between *H. t. florencia* and *H. t. linaresi*, some preference is observed,
leading to an estimated *RI<sub>colour</sub>=0.27/0.35*.

245

### 246 Male choice

At high divergence, male preference for conspecific over heterospecific living females is stronger than observed with models, suggesting that a wider range of proximal cues are available, such as chemical signals or behavioural cues, and influence male courtship decision
leading to a higher RI (*RI<sub>malechoice</sub>=0.64-1*).

251

252 The use of proximal vs. long-range visual cues by males seems to depend on the direction of 253 the hetero-specific interaction: *H. melpomene* males indeed respond to wing models with a very 254 strong choice based on colour cues, and appear to show little discrimination when presented 255 with females with similar pattern (timareta). By contrast, H. cydno or H. heurippa males show 256 some discrimination against *H. melpomene* models, but it is weaker than for *H. melpomene* 257 males [18,33], and choice is generally enhanced by real-females cues. Moreover, in the mimetic 258 pair, H. t. thelxinoe males strongly prefer conspecific over heterospecific females using close 259 range chemical cues [21].

260

At intermediate and at low divergence, a limited amount of reproductive isolation due to male courtship behaviour is sometimes observed ( $RI_{malechoice}=0.5-0.78$  and 0-0.4, respectively) although the strength of isolation is generally weaker and more asymmetric than at high divergence.

265

#### 266 Achieved mating

At high divergence, the total index of sexual isolation is high for all pairs and in both directions of crosses ( $RI_{mating}$ =0.78-1). RI estimated using achieved mating is higher than when estimated based on model or live-female experiments, suggesting that female response and contact interactions (beyond male courtship) also contribute to pre-mating isolation, especially for the mimetic pairs (preventing *TxM* heterospecific mating for instance).

At intermediate divergence, isolation is generally high, though asymmetric, such as between *H*. *c. cordula* and *H. heurippa* ( $RI_{mating}$ =0.56/0.98) or between allopatric populations of *H. melpomene* ( $RI_{mating}$ =0.65/1). *RI* estimated on total mating is again higher than *RI* estimated on experiments with models, suggesting that close-range cues and male-female interactions may also be relevant at intermediate divergence.

278

By contrast, at low divergence between the parapatric races *H. t. florencia/H. t. linaresi*, reproductive isolation is much lower. It is observed only in one direction (TnxTf,  $RI_{mating}$ =0.48) and largely explained by colour pattern preference.

282

## 283 Post-mating isolating barriers

F1 Egg and larval survival

285 At high divergence, F<sub>1</sub> hybrids show no significant reduction of hatch rate.

286

Oviposition preferences for different *Passiflora* hosts generally constitute an axis of differentiation between the melpomene and the cydno-clade, *H. melpomene* being generally more specialised than its local cydno-clade counterpart [17,36,46] with some exception in Colombia where *H. melpomene* has a diverse range of oviposition plants [47].

291

Hybrid larval survival has only been tested in three pairs at high divergence but shows no significant reduction of survival, leading to a null contribution to reproductive isolation. This suggests neither hybrid viability breakdown related to genetic incompatibilities nor incapacity to metabolize the host-plant are acting in these pairs. For *H. c. cordula/H. m. melpomene* and *H. heurippa/H. m. melpomene* hybrids (Table.S7), this result corresponds to expectations since the hybrids were fed on a common host-plant (*P. oesterdii*). However, this may be surprising for the *H. t. thelxinoe/H. m. amaryllis* hybrids, which were fed on the maternal host-plant(Table.S4).

300

301 Testing survival in experimental conditions with unlimited access to food, fewer parasites and 302 no competition might have underestimated the importance of efficient host-plant use in hybrid 303 growth. We can note for instance, that, in semi-natural conditions, early stage *H. melpomene* 304 larvae from central America had a higher survival rate on P. menispermifolia than on other 305 Passiflora species [46] while in insectaries, similar growth rates have been achieved for various 306 species of Passiflora [48]. In Peru, several preliminary attempts of feeding H. m. amaryllis 307 larvae and some hybrids (back-crosses towards H. m. amaryllis) with P. edulis or P. granadilla 308 (well-accepted by *H. t. thelxinoe*) led to higher mortality rate.

309

#### 310 F<sub>1</sub> adult survival

Adult mortality due to predation was estimated only for the hybrids between *H. c. chioneus/H. m. rosina*. Its contribution to isolation was significant with *RI*=0.35, but lower than that due to
pre-mating barriers.

314

315 In the co-mimetic pairs,  $F_1$  hybrids are visually similar to the parents and predation is not 316 expected to participate in reproductive isolation.

317

In other cases, F<sub>1</sub> hybrids may also be similar to one parent (*H. c. galanthus/pachinus* hybrids being like *H. c. galanthus* [19], *H. heurippa/H. m. melpomene* hybrids being similar to *H. m. melpomene* [24], and heterozygotes at the K locus of *H. cydno alithea* are white [32], which introduces asymmetry in isolation because they are expected to survive better in one habitat. For instance, mark-resight experiments on *H. cydno alithea* [30] let us estimate predation

```
against white morphs in areas dominated by the yellow mimic, suggesting a mean RI_{adult survival}
due to predation against F<sub>1</sub> hybrids around 0.18 (0.36 and 0, respectively in areas dominated by
yellow or white).
```

326

```
327 F<sub>1</sub> mating ability: sexual selection against F<sub>1</sub> hybrid
```

328 At high divergence, in non-mimetic as well as co-mimetic pairs, mate discrimination against  $F_1$ 329 hybrids appears as an additional isolating barrier although its strength is highly variable and 330 asymmetric, depending on the parental partner tested (*RI<sub>F1success</sub>*=0-0.87, Table.S5-9).

331

At intermediate divergence, for *H. c. galanthus/H. pachinus* F1 hybrids, whose phenotype is similar to *H. c. galanthus* parent, mating discrimination is also exerted by *H. pachinus* males, resulting in asymmetric isolation ( $RI_{F1success}$ =0/0.94).

335

### 336 Fertility of F<sub>1</sub> adults

At high divergence, the estimated isolating strength of hybrid sterility is intermediate compared to other factors and asymmetric ( $RI_{fertility}$ =0.27-0.48 in one direction,  $RI_{fertility}$ =0-0.34 in the other direction).

340

F<sub>1</sub> males are fully fertile except for the allopatric pair *H. c. chioneus/H. m. melpomene* which
show a slight reduction in fertility [23].

343

Female  $F_1$  fertility is more complex. All studies involving crosses between a *H*. *cydno/heurippa/timareta* mother and a *melpomene* father found complete sterility of female  $F_1$ (Table.S4)[23,24]. In the other direction of crosses, i.e. a *melpomene* mother and a *cydno/timareta/heurippa* father,  $F_1$  fertility is highly variable. At the extremes, all *H. m.*  *melpomene* X *H. heurippa* females tested were fully fertile [24] whereas *H. m. melpomene*(French Guiana) X *H. c. chioneus* (Panama) females were all sterile [23]. For most other pairs,
partial fertility was reported [23,42](Table.S10) with intriguing non-uniform pattern. For
instance, in *H. melpomene* X *H. timareta* hybrids, some hybrid females had a lower fertility
than pure females, while others were completely sterile and others completely fertile
(Table.S4).

354

At intermediate or low divergence, no significant reduction of fertility was found except for the allopatric pair *H. m. rosina* (Panama)/*H. m. melpomene* (French Guiana) with lower fertility for  $F_1$  female (and possibly males) hybrids [49], resulting in *RI*<sub>fertility</sub>=0.43 in one direction.

358

# 359 **Discussion**

Quantifying reproductive isolation throughout a speciose clade of *Heliconius* butterflies shows that different levels of genetic divergence correspond to marked quantitative and qualitative differences in reproductive isolation. Higher divergence is associated with both the accumulation of additional barriers and the strengthening of a common set of barriers, although some axes of differentiation are quite labile depending on the ecological context.

365

The diversity of taxa at different levels of divergence and strengths of RI has been characterised as a 'speciation continuum'. This does not necessarily imply that these actually represent sequential stages in speciation, nor that any particular example is on an inevitable path towards complete speciation. For example, different stages might be at equilibrium between divergence and gene flow or correspond to qualitatively different pathways to differentiation. Nevertheless, the 'speciation continuum' is useful and perhaps analogous to the manner in which those studying the evolution of complex structures, such as the eye or the flagellum, infer past evolutionary trajectories from the comparative study of apparently intermediate structures in extant animals. Such examples provide support for the plausibility of a particular route towards a complex structure, or in the present case a route towards complete speciation, but do not prove that any particular evolutionary route has been taken in nature. Our analysis therefore allows assessment of the roles that different factors might take in shaping divergence, while accepting that the current array of divergence states does not necessarily represent successive stages along a unique path to speciation.

380

### 381 Is reproductive isolation driven by a single trait or multidimensional factors?

Isolation in the face of gene flow requires that certain factors counter the effects of recombination between alleles that characterise diverging taxa [8,50-52]. This might include strong disruptive selection on a single (large-effect) trait [53], an association between ecological divergence and reproductive isolation (via a 'magic' trait for instance [28]), or the coupling of several isolating barriers [50]. Diverging *Heliconius* taxa showing a shift in colour pattern meet all those criteria, making colour pattern divergence a major initiator and driver of reproductive isolation in this group [27, 34].

389

390 Given that colour-pattern differentiation underlies the main isolating barriers (predation, mate 391 choice, habitat partitioning) and that all those barriers operate at low, intermediate and high 392 divergence, one may wonder whether increased isolation results from the "stronger selection" 393 scenario [53], under which barriers associated with colour pattern differences are strengthened 394 along the continuum of divergence. This is the case, for instance, in *Pundamilia* cichlid fish, in 395 which increased isolation is associated with increased divergence on one main axis of 396 differentiation: male coloration in relation to habitat transparency [54]. The alternative 397 hypothesis would be that increased isolation is the product of "multifarious selection" [53], with the addition of independent traits and more isolating barriers at higher divergence [55,56]. For
instance, between colour-pattern races of poison frog, isolation is much higher for a pair which
also exhibit size differences associated with habitat specialization [57].

401

402 Those predictions can be tested by comparing the strength of the barriers potentially associated 403 with colour pattern divergence along the *Heliconius* continuum. The lower stages of divergence 404 reported in *Heliconius* correspond to wing-pattern races, for which selection causes genetic 405 differentiation only around wing-patterning loci [38] and maintain weak isolation. At this stage, 406 selection on different mimicry associations maintains spatial segregation through predation 407 against migrants [30,31], and is likely to cause post-mating isolation through predation against 408 non-mimetic hybrids. The third barrier, male preference based on colour, is already acting at 409 low-divergence but its contribution is variable and asymmetric. What is the fate of those barriers 410 at higher divergence? Isolation due to predation against hybrids has not been quantified in 411 many pairs of taxa. It does appear stronger for the H. c. chioneus x H. m. rosina hybrids (high divergence), than for H. c. alithea F1 (low divergence) for instance. It is worth noting that 412 413 predation itself is of the same magnitude in both cases, reducing the survival of any deviant 414 form by about 30%. RI due to predation is thus lower in C. alithea hybrids because they are 415 similar to one parent (white) while H. c. chioneus x H. m. rosina hybrids differ from both 416 parents and suffer from predation in all habitats. Therefore, isolation against hybrids depends 417 on dominance and segregation of colour patterns in hybrids, with the hybrid being generally 418 more different at higher level of divergence (except for the mimetic pairs). Habitat 419 partitioning gets stronger at high divergence. Just like for pairs of taxa at low divergence, fine-420 scale partitioning between taxa at high divergence may follow the distribution of their co-421 mimics, as observed for instance between H. c. chioneus and H. m. rosina across the transition 422 from closed forest to edge habitat [22]. However, habitat specialization for closed forests is also

423 exhibited by other members of the cydno clade such as H. timareta (co-mimic with H. 424 *melpomene*) or *H. heurippa* (no co-mimic), suggesting that microspatial partitioning at high 425 divergence is not only conditioned by mimicry, but also by other ecological preferences which 426 remain unknown but may involve abiotic conditions, adaptation to altitude or host-plants. The 427 component of mate choice clearly attributable to visual cues, deduced from experiments with 428 models, is generally strengthened at high and intermediate divergence, though not consistently 429 between species. In addition, assortative mating is likely to involve a chemical component for 430 most pairs of taxa at high divergence. Again, as hybrids tend to be quite different from parental 431 species at higher divergence, sexual selection against hybrids is also stronger at high 432 divergence. Overall, increased isolation does involve a strengthening of isolating barriers 433 directly linked to colour pattern differences, but higher RI also rests largely on the addition of 434 other isolating dimensions.

435

436 To assess the relative importance of colour pattern shift at later stages of speciation, it is also 437 useful to consider species pairs that do not exhibit colour pattern divergence, such as the co-438 mimics *H. timareta/H. melpomene*. Genomic evidence suggests that these species were initially 439 divergent in colour pattern and became co-mimics after secondary introgression of wing pattern 440 alleles from H. melpomene into H. timareta [58]. Under this scenario, if colour pattern 441 divergence plays an important role in the isolation of species at higher divergence, reproductive 442 isolation is expected to be weakened secondarily by mimicry and gene flow. Such collapse of 443 differentiation has sometimes been observed, notably between pairs of taxa that rely on one 444 main axis of differentiation, habitat-related for instance [59]. Compared with H. c. chioneus/H. 445 *m. rosina*, the co-mimics *H. t. thelxinoe/H. m. amaryllis* indeed display a ~2% reduction of total 446 estimated RI and a slightly lowered genomic divergence [60]. Both in the Colombian and 447 Peruvian mimetic pairs, natural hybrids are also marginally more frequent (1-3%) [17, 36]. This

448 reduction of RI between co-mimics follows the prediction but shows that lifting the wing-449 pattern barrier has a rather limited effect on species differentiation because RI relies on multiple 450 other isolating mechanisms (habitat specialisation, assortative mating based on chemical 451 communication [21], partial hybrid sterility and likely host-plant divergence). This implies that 452 reproductive isolation between pairs at a high level of divergence is strong enough to allow the 453 secondary loss of certain barriers to gene flow, in this case via the introgression of wing-pattern 454 alleles, without compromising genome-wide differentiation. Consistent with this idea, but at 455 yet deeper levels of divergence within the genus Heliconius, co-mimics H. erato and H. 456 melpomene, are visually attracted to each-other yet never hybridize, owing to strong differences 457 in other courtship signals and natural history [61]. Generally, our analysis supports the 458 hypothesis that multiple diverging dimensions add cumulatively to reproductive isolation and 459 favour the completion of speciation in the face of gene flow [53].

### 460 How do isolating mechanisms evolve?

The continuum of reproductive isolation spanned in this study also corresponds to a continuum of time since divergence, raising the questions of how the multiple barriers accumulate through time, which result from selection, which are a by-product of isolation through drift, and what is the relative importance of ecological and non-ecological processes.

465

Pre-mating sexual isolation stands out as one of the strongest barriers at all levels of divergence and gets stronger along the continuum of divergence. This observation is consistent with the rapid evolution of pre-mating isolation generally reported for speciation with gene flow [2], in fish [7,62], drosophila [44] or plants [55]. As with darter fish [63], the rapid evolution of strong assortative mating in *Heliconius* appears to be associated with sexual selection, notably for chemosensory traits [64] which, as indicators of mate quality, are common targets of sexual selection [65]. 474 An increase in pre-zygotic isolation between hybridizing populations may also reflect 475 reinforcement, under selection against interspecific mating [66]. In Drosophila for instance, the 476 fast evolution of mate choice has been linked to reinforcement processes, with pre-mating 477 isolation being stronger for pairs with geographic overlap [44] and pairs with higher 478 hybridization costs [67]. Here, higher stages of divergence are characterized by a decrease in 479 hybrid fitness, such that stronger pre-mating isolation may reflect stronger selection against 480 hybridization. In addition, the higher geographic overlap seen in pairs at high divergence also 481 provides more opportunities for selection against hybridization to operate. Evidence for 482 reinforcement comes from higher pre-mating isolation observed in the sympatric H. c. 483 chioneus/H. m. rosina than in the allopatric H. c. chioneus/H. m. melpomene as well as an 484 increased mate choice between H. c. galanthus and H. pachinus in populations close to the 485 contact zone [39].

486

487 Under a hypothesis of reinforcement, premating isolation comes as a response to hybrid 488 unfitness, so it may seem paradoxical to observe rather weak or moderate post-mating barriers. 489 It could be that their current contributions do not reflect their past importance or that the 490 accumulation of several weak barriers is sufficient to select for assortative mating. Our analysis 491 may also underestimate the strength of extrinsic post-mating barriers, which are experimentally 492 more difficult to assess. Notably, little is known about the ecology of hybrids, and poor hybrid 493 performance may represent a significant barrier when parental species occur in markedly 494 different microhabitats (e.g. altitude for *H. timareta/H. melpomene*).

495

Habitat specialisation associated with fine-scale spatial segregation and host-plant divergenceis observed for all pairs at high divergence but for none at low divergence. Interestingly,

498 parapatric species at intermediate divergence do not show clear habitat or host-plant differences 499 either, suggesting that habitat specialisation might be one of the key barriers allowing 500 geographic overlap and leading to high divergence. Such a transition from parapatric, 501 ecologically-similar morphs to overlapping microhabitat-specialized taxa is also reported along 502 the stickleback speciation continuum [7] and perhaps constitutes a tipping point in the evolution 503 of isolation [10].

505 The last post-mating barrier widely observed at high divergence but generally absent at lower 506 levels of divergence is hybrid female sterility (with the exception of allopatric races of H. 507 *melpomene* [49]). This result is quite general in the literature: when speciation occurs with gene 508 flow, post-mating incompatibilities tend to accumulate more slowly than ecological and pre-509 mating isolation [44,62,68], and follow Haldane's rule by first affecting the heterogametic sex 510 [69]. Generally, the strongest isolation was found between allopatric pairs coming from distant 511 areas (Panama VS French Guiana) whereas in sympatry, F<sub>1</sub> female sterility can be variable, 512 from fully-sterile to fully-fertile, suggesting that sterility is variably affected by local gene flow. 513 Heliconius female sterility is typically caused by interactions between the Z chromosome and 514 autosomal loci [23,24,49]. Among sympatric pairs of taxa at high divergence such as H. 515 timareta/H. melpomene or H. cydno/H. melpomene, Z chromosomes are very divergent while 516 autosomes show a strong signal of admixture [60]. Admixture might prevent the accumulation 517 of incompatibilities on autosomes (or may allow its purge following secondary contact), 518 therefore limiting the evolution of female sterility. Such a hypothesis would question the 519 stability of this intrinsic barrier, traditionally assumed to be irreversible.

<sup>504</sup> 

#### 521 Conclusion

In summary, we have quantified most of the known components of reproductive isolation across 522 523 a recent adaptive radiation. Contrasting pairs of hybridizing taxa showing different levels of 524 divergence suggests that speciation involves the strengthening of some isolating barriers but, 525 importantly, seems to require the accumulation of additional barriers. Indeed, the synergistic 526 action of wing pattern shifts and other isolating mechanisms appears to be important for 527 reproductive isolation in *Heliconius*, especially at early stages of divergence. Nevertheless, the 528 case of co-mimetic hybridizing species reveals that certain isolating barriers, and especially 529 wing pattern differences, may in fact be quite labile or partially reversible. This shows that a 530 seemingly key factor in the early stages of differentiation may have its role taken over by other 531 barriers at later stages of divergence. A key promoter of the stability and completion of species 532 divergence thus appears to be the multidimensionality of reproductive isolation.

533

# 534 Author's contributions

535 CM and MJ designed the analysis. CM performed the meta-data analysis and the new data 536 acquisition on the Peruvian species. CS acquired new data on the Colombian species. RM and 537 CJ studied the Panamanian species. CM and MJ wrote the manuscript with contributions from 538 all authors. All authors gave final approval for publication.

539

# 540 Acknowledgments

This clade-comparison has been made possible thanks to all the experiments and investigations led by *Heliconius* researchers in the past years. We are grateful to them for allowing us to reanalyse their data. We thank the Museo de Historia Natural de Lima, the Ministerio de la Agricultura, the SERNANP-BPAM, PEHCBM-ACR for collection and export permits. We thank Marianne Elias, Ewan Twomey and an anonymous reviewer for helpful comments onthis manuscript.

547

# 548 Funding

- 549 This work was supported by ERC Starting Grant Stg-243179 (MimEvol) and French Research
- 550 Agency grant ANR-12-JSV7-0005 (HybEvol) to MJ. CS was funded by the Universidad del
- 551 Rosario FIUR grant QDN-DG001 and COLCIENCIAS (Grant FP44842-5- 2017). RM was
- 552 funded by a Research Fellowship at King's College, Cambridge.

# 554 Table 1: Strength of reproductive isolation associated with each barrier to gene flow

555 RI ranges from 0 (non-significant barrier), to 1 (full isolation). For each pair of species, the two 556 lines correspond to the two possible directions of heterospecific mating with the female/mother 557 given first. Barriers that could not be estimated are not shown. We indicated by a dash barriers 558 that could not be estimated but are likely non-significant. The grey scale describe the continuum 559 of divergence with the "high" category corresponding to pairs of taxa involving a representative 560 of the melpomene-clade and the cydno-clade, and "intermediate" and "low" including pairs of 561 taxa belonging to the same clade, respectively with (\*) and without ("n.s") significant genetic 562 divergence [14,32,41].
