**Abstract**

In the last 15 years, hip arthroscopy has become more popular in addressing femoroacetabular impingement (FAI) because of its minimally invasive approach. However, assessing the adequacy of bone resection when correcting FAI can be difficult because the visualisation and spatial awareness of the joint are poor. The recent development of technology in the field of computer-assisted/ navigation and robotic surgery in orthopaedics as a resource for preoperative planning and intraoperative assistance has been widely reported. As this technology is expected to upgrade surgical planning and techniques, decrease human error and improve operative results by precisely defining the divergent anatomy and kinematics of the hip joint, they could also prove beneficial in the field of arthroscopic FAI surgery. This review attempts to bring the reader up-to-date with the current developments in the field, discuss our experiences with navigation and robotics and provide a platform for future research in this arena.

## 52 Introduction

53 Femoroacetabular impingement (FAI) occurs when the hip joint has an abnormal  
54 shape at the femoral head-neck junction (cam-type) or at the acetabular rim of the  
55 pelvis (pincer-type). It has been recognised as a major risk factor that may lead to  
56 the development of early labral and cartilage damage in the non-dysplastic hip (1-4).  
57 Several clinical studies have shown that surgical correction of these osseous  
58 abnormalities improves clinical function and relieves hip pain (3,5-7). However, in  
59 patients with FAI, due to the complex 3D shape of the offending lesion and the  
60 large soft-tissue mantle around the hip joint, the arthroscopic view of the working  
61 area can be restricted (8). In addition, evaluation of the sphericity of the femoral  
62 head in the treatment of cam-type FAI during hip arthroscopy is difficult (9,10); it is  
63 usually done by means of surgical templates (femoral spherometer gauges) during  
64 open surgical dislocation.

65

66 Recently, computer-assisted navigation and modelling have emerged as a potential  
67 solution to improve the preoperative planning for FAI, including determination of  
68 the location and size of pincer/cam lesions, as well as to increase the accuracy of  
69 intraoperative correction of the osseous deformity. In this review, we will firstly

70 outline the recent developments of computer-assisted surgery in orthopaedics, the  
71 anatomy of FAI and the current limitations of arthroscopic FAI surgery. We will then  
72 describe the evolution of computer-assisted hip arthroscopy to address these  
73 limitations, which is divided into two parts; preoperative planning/assessment tools  
74 and intraoperative navigation programmes. Lastly, the future of robot-assisted hip  
75 arthroscopy is discussed. The aim of this review is to outline the current conditions  
76 and challenges in computer-assisted arthroscopic FAI surgery.

77

## 1. Computer-assisted surgery in orthopaedics

The purpose of computer-assisted technology in orthopaedics is to provide patient-specific tools that allow for the reliable implementation of preoperative surgical plans in the operating theatre (11). The ideal goal of this technology would be to integrate high-precision preoperative surgical plans based on prior CT or MRI with actual surgical treatment procedures, by accurate placement of operative tools with quantitative feedback to assess the execution of the surgical plan.

These days, there is little doubt that computer-assisted surgery produces more accurate and precise results, and reduces the learning curve in some types of orthopaedic surgeries, including lower limb joint replacement (total hip replacement and total/unicondylar knee replacement), anterior cruciate ligament reconstruction and trauma and spine surgery (12-16). However, there have not been enough data to support improved outcomes after these navigated operations thus far. For example, although navigated total knee replacement is one of the most popular applications of computer-assisted technology in orthopaedics, no study has been available to validate this technology and prove its long-term benefits (17). Also, while navigation technology has been reported to improve the positioning of

96 components in unicondylar knee replacement and the acetabular cup positioning in  
97 total hip replacement, the assumed benefits of technical precision and  
98 reproducibility have not to be correlated with better objective and subjective  
99 clinical outcomes yet (14,18). The cost of these systems and the learning curve  
100 associated with these new technologies should also be solved before extended  
101 application.

## 2. Pathoanatomy of FAI

The term 'femoroacetabular impingement' was first used in English-language literature in 1999 (19). By definition, FAI is a result of bone abutment of the femoral neck and the acetabulum. Though two distinct types of FAI have been recognised (cam and pincer), most patients present with clinical and radiographic findings which relate to both deformities. Cam impingement refers to a decrease in the femoral head-neck offset, in other words, asphericity of the femoral head-neck junction, which causes a prominent osseous lesion that impinges on the acetabulum. The location of impingement is unique and defined by the proximal-distal, medial-lateral and circumferential margins of the loss of offset; most cam lesions impinge with flexion, adduction and internal rotation of the hip. On the other hand, focal pincer impingement lesions cause abnormal edge-loading of the acetabular rim, and it can occur with focal or global acetabular retroversion, coxa profunda or protrusion acetabuli (20,21).

It is widely believed that the onset of osteoarthritis (OA) relates to the local mechanical environment of a joint (22,23). In terms of the hip, cam-type FAI is recognised as an early cause of joint dysfunction, including pain generation,

1  
2  
3  
4  
5  
6 120 degeneration and tearing of the labrum which leads to OA (20,24-27). In the patient  
7  
8  
9 121 with FAI, characteristic injury to the labrum and cartilage has been observed, and it  
10  
11 122 is thought to reflect repetitive micro-trauma from the abnormal osseous  
12  
13  
14 123 morphology. The labrum has several functions, such as hip stability, cartilage  
15  
16  
17 124 nutrition, augmentation of femoral head coverage and a so-called joint sealing  
18  
19  
20 125 effect (28,29). The labrum is often the first structure to be affected by pincer  
21  
22  
23 126 impingement due to mechanical impingement between the femoral neck bone and  
24  
25  
26 127 acetabulum with subsequent degeneration or ossification. In contrast, in typical  
27  
28  
29 128 cam impingement, there is early delamination of the cartilage with labral  
30  
31 129 degeneration and detachment over time, as a result of chronic repetitive stress (1).

32  
33  
34 130

35  
36  
37 131 In the surgical management of FAI, both open and arthroscopic approaches can be  
38  
39  
40 132 used. As an open technique, open surgical dislocation of the hip was described to  
41  
42  
43 133 minimise iatrogenic injury to the articular surface and obtain a wide view of the hip  
44  
45  
46 134 joint safely (30). It is, however, not without risks, including non-union after  
47  
48  
49 135 trochanteric osteotomy, avascular necrosis due to disruption of femoral head blood  
50  
51 136 supply and increased morbidity with a large amount of soft tissue dissection (31).  
52  
53  
54 137 Based on this, hip arthroscopy has evolved to correct osseous morphology which  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 138 causes impingement, as well as treat both chondral and labral lesions in a minimally  
7  
8  
9 139 invasive manner (32-34). Several authors have reported on arthroscopic treatments  
10  
11  
12 140 for FAI-related pathology with favourable clinical outcomes (32,35-37), but there  
13  
14  
15 141 have been no long-term outcomes. Systematic reviews assessing differences in  
16  
17  
18 142 outcomes between the arthroscopic and open treatment of FAI have also been  
19  
20  
21 143 reported (34,38), and they have concluded that open techniques to address FAI and  
22  
23  
24 144 labral tears are not superior to arthroscopic methods.

146 **3. Current limitations of hip arthroscopy for FAI**

147 As our understanding of FAI continues to improve, there is an increased interest in  
148 computer-assisted planning and navigation to treat abnormalities associated with  
149 FAI. The current limitations of arthroscopic FAI surgery can be divided into two  
150 perspectives: preoperative assessment and intraoperative execution. While the  
151 long-term clinical outcome may be multifactorial, a reproducible and accurate  
152 surgical correction of the deformity may be one of the few variables with FAI which  
153 is surgeon-controlled. Therefore, the challenges of preoperative characterisation of  
154 the mechanical deformities, as well as the difficulties in intraoperative exposure and  
155 correction of impingement regions, make computer-assisted surgical technologies  
156 particularly useful.

158 ***Preoperative planning***

159 Preoperative assessment tools, which include imaging modalities such as  
160 radiography and CT and MRI scanning, are all aimed at providing the surgeon with a  
161 patient-specific reconstruction of the osseous anatomy as well as a proper diagnosis.  
162 Currently, preoperative planning for arthroscopic FAI is based on these static  
163 anatomical models which characterise cam and pincer lesions. It is important to

164 recognise the osseous anatomical anomalies when planning arthroscopic FAI  
165 surgery; in a recent CT-beased study Dolan et al (39) reported that 90% of patients  
166 with symptomatic labral tears had structural abnormalities, such as femoral  
167 retroversion or excessive anteversion, coxa valga or acetabular dysplasia which  
168 includes lateral and/or anterior under-coverage.

169  
170 Today, the alpha angle is the most used tool for the anatomical surgical planning of  
171 FAI. Alpha angle is defined by the axis of the femoral neck and a line connecting the  
172 centre of the femoral head to the anterior extent of the concavity of the femoral  
173 neck in an MRI slice which is parallel to the axis of the neck and passing through the  
174 centre of the femoral head (40). Usually, an alpha angle  $< 50^\circ$ , or a reduction of the  
175 alpha angle by  $20^\circ$  (in cases where the alpha angle is very large) is recommended as  
176 a target for surgical correction, because this would result in satisfactory restoration  
177 of femoral head-neck offset (41). The alpha angle has also been shown to correlate  
178 with increased chondral damage, labral injury, decreased range of movement  
179 (ROM) and other preoperative symptoms (42,43). It is also useful in assessing  
180 surgical correction postoperatively (44). There are, however, some drawbacks to  
181 using the alpha angle as a tool. First, as the maximal loss of the head-neck offset is

1  
2  
3  
4  
5  
6 182 present at different locations in different patients (45). 2D measurement is not  
7  
8  
9 183 enough to assess the anatomical variances. Secondly, it does not take the length of  
10  
11  
12 184 the cam lesion into account. The resection should be advanced into the trochanteric  
13  
14  
15 185 fossa in the case of a large bump. Thirdly, the alpha angle does not always correlate  
16  
17  
18 186 with the clinical ROM. Brunner et al(46) reported that cam-type FAI patients with  
19  
20  
21 187 insufficient offset correction showed a slightly better internal rotation than patients  
22  
23  
24 188 with satisfactory offset restoration. Lastly, a pathological value of the alpha angle  
25  
26  
27 189 itself has been questioned. Clohisy et al (47) could not define an alpha angle  
28  
29  
30 190 threshold beyond which a pathological diagnosis could be made after evaluating  
31  
32  
33 191 the alpha angle in both FAI patients and normal controls.

34 192

35  
36  
37 193 ***Intraoperative execution***

38  
39  
40 194 The learning curve associated with arthroscopic FAI surgery is often referred to as  
41  
42  
43 195 ‘steep’ (48,49). It is often difficult to undertake a preoperative plan correctly, as it  
44  
45  
46 196 requires not only a high level of arthroscopic skill and good visualisation but also  
47  
48  
49 197 precise identification of the margins of the osseous bump lesion and a proper  
50  
51  
52 198 decision on the amount of bone resection. Even in the hands of experienced hip  
53  
54  
55 199 arthroscopy surgeons, who have achieved adequate exposure, the margins of the

impingement lesion are not always obvious. Patient positioning, cannulation, visualisation and osseous resection are all factors which could lead to potential technical errors.

203

Hip arthroscopy surgeons usually combine arthroscopic appearance with fluoroscopy to perform an intraoperative assessment of an adequate resection. The problem with this method is that both of them are a 2D modality and the 3D morphology is, therefore, constructed only in the surgeon's brain without any objective assessment. Osseous abnormalities are often under-resected, and this is a major cause for revision hip arthroscopy, accounting for up to 78% to 90% of all unsuccessful arthroscopic FAI surgery (50,51). It is common for inexperienced surgeons to stop the osseous resection once an adequate image is obtained on fluoroscopy but some cam lesions extend posteriorly or distally and further internal rotation or an accessory portal may show an inadequate resection. Surgeons should bear over-resection of the bone in mind as well. Over-resection of a pincer lesion can result in iatrogenic dysplasia due to acetabular under-coverage, and postoperative instability and dislocation have been reported to be linked to over-resection (52,53). Over-resection beyond the margins of a cam lesion can

218 damage the cortical bone support of the femoral neck, which may lead to iatrogenic  
219 fracture (54). Moreover, in the posterolateral part of the proximal femur, the blood  
220 supply to the epiphysis can be damaged by excessive reaming, leading to avascular  
221 necrosis (55). These problems reinforce the need for computer-navigated surgical  
222 tools which guide surgeons sufficiently during the operation.

For Peer Review

#### 223 4. Current navigation technology

##### 224 *Preoperative computer aided assessment*

225 When assessing the deformity and planning for surgical correction preoperatively,  
226 dynamic manipulation of the image using applied algorithms or computer software  
227 as well as virtual 3D reconstruction and visualisation of the hip joint may be  
228 beneficial for surgeons.

229

230 Some non-invasive preoperative software programmes which help surgeons localise  
231 the zone of impingement, quantify the volume of resection and predict  
232 postoperative ROM using both anatomical and kinematic data have been reported  
233 on.

234

235 ● The first comprehensive preoperative assessment tools ('HipMotion') were  
236 developed by Tannast et al (56) in 2007. The system performs a CT-based 3D  
237 kinematics analysis of the hip joint to define zones of impingement and then  
238 predict improvement in ROM after a virtual resection. It was made to address  
239 the need for an accurate kinematic preoperative plan and enhanced visual  
240 guidance to the surgeon. The native preoperative ROM is calculated by collision

241 algorithms which determine ROM based on points at which impingement  
242 occurs after defining the hip centre. Then, the system performs a virtual surgical  
243 femoral and acetabular resection which prevents an impingement within  
244 normal physiological ROM. After that, using the new parameters, virtual  
245 postoperative ROM is simulated by reconstructing the hip joint to assess the  
246 efficacy of the planned procedure (57). They used concentric range of motion  
247 simulation and did not take any hip translations at the end of range of motion  
248 into account. The system offers the advantage of calculating the volume of  
249 resection based on an impingement-free postoperative ROM, not a desirable  
250 postoperative alpha angle. Validation of this software was performed by  
251 comparing the virtually predicted ROM with the actual measured ROM of  
252 cadaveric hips. Authors also compared the virtual ROM of normal hips with FAI  
253 hips and reported that patients with FAI had significantly decreased flexion,  
254 internal rotation at 90° of flexion and abduction (56).

- 255 ● Using the 3D software ‘Mimics’ (Materialise, Belgium) to analyse 13 hips with  
256 cam-type impingement, Audenaert et al (58,59) reported that during internal  
257 rotation in 90° of flexion, the central-medial portion of the cam lesion was  
258 found to abut against the anterosuperior quadrant of the acetabular cartilage.

259 Bedi et al (60) measured clinical ROM and calculated virtual ROM using Mimics  
260 in FAI patients before and after arthroscopy, and reported excellent correlation  
261 in the postoperative improvement between clinical ROM and virtual ROM, with  
262 no significant differences by paired Student's t-tests. Mimics is a segmentation  
263 software package and does not allow virtual range of motion simulation. Both  
264 Audenaert et al and Bedi et al used dedicated software scripts to perform the  
265 motion simulation and calculated zones of impingement, and bony shapes were  
266 segmented from the CT scan with the Mimics software.

- 267 ● 'Articulis' (Clinical Graphics, Netherlands) is also a software which automatically  
268 performs the 3D segmentation of the CT scans, assesses the deformity, plans  
269 for surgical correction and carries out dynamic manipulation of the image. The  
270 reliability and accuracy of this system in determining the presence of movement  
271 limiting deformities of the femoroacetabulum was validated using a cadaveric  
272 model with artificial cam deformities (Figure 1) (61).
- 273 ● The 'Dyonics PLAN Hip Impingement Planning System' (Smith & Nephew, USA)  
274 provides not only a virtual 3D reconstruction and visualisation of the hip joint  
275 but also a platform for intraoperative assistance by performing virtual  
276 correction and creating a virtual fluoroscopic image that can be compared with

1  
2  
3  
4  
5  
6 277 intraoperative fluoroscopic images, thus verifying adequate bony resection.  
7  
8  
9 278 Milone et al (62) demonstrated the effectiveness of this software compared  
10  
11 279 with traditionally reformatted CT scans and plain radiographs.  
12  
13  
14 280 They can also be used postoperatively for the assessment of the amount of osseous  
15  
16  
17 281 shaving in the cam or pincer lesions.  
18  
19  
20 282  
21  
22 283 There are, however, some limitations to the use of these systems. The data are  
23  
24  
25 284 based on a predefined centre of rotation around which the femoral head moves,  
26  
27  
28 285 and they therefore ignore additional translations or detected collisions. Stated  
29  
30  
31 286 another way, the software does not account for the translation which occurs with  
32  
33  
34 287 hip movement, weight-bearing and muscular activation (63). Furthermore, the  
35  
36  
37 288 CT-based model only allows for osseous impingement and its surgical correction  
38  
39  
40 289 with an osteoplasty of the acetabular and femoral bone. It does not account for  
41  
42  
43 290 impingement of periarticular soft tissues such as labrum. Soft-tissue laxity or  
44  
45  
46 291 impingement can affect ROM and clinical outcomes after surgical intervention.  
47  
48 292 Therefore, these systems may overestimate the potential gains in movement that  
49  
50  
51 293 can be achieved after surgery. In addition, there have been no comparative trials to  
52  
53  
54 294 date determining the superiority of using these systems in the clinical setting.

295

296 ***Intraoperative navigation***

297 Navigation programmes guide the surgeon to precisely reproduce preoperative  
298 plans intraoperatively. The components of these types of navigation systems  
299 generally consist of these three parts:

- 300 ● Measurement devices to trace the surgical tool;
- 301 ● display device to show information about the surgery;
- 302 ● marker on the surgical tool.

303

304 Intraoperative navigation requires matching the preoperative 3D-CT scan to the  
305 intraoperative situation. This registration process to establish correspondence  
306 between both situations can be image-based (using fluoroscopy) or imageless  
307 (using a digitised pointer to mark anatomical landmarks on the bone). Both  
308 image-based and imageless protocol require an osseous pin with a calibration  
309 marker attached to it that can record the motions of the femoral segments and  
310 adjust the navigation feedback accordingly, which avoids the necessity to repeat  
311 the registration step each time the femoral position is changed. Example of  
312 intraoperative navigation is shown in Figure 2.

313

314    Developments and outcomes of various intraoperative navigation programmes  
315    have been reported recently.

316    ● Brunner et al (46) uploaded preoperative CT images of patients into a modified  
317    version of BrainLAB Hip-CT (BrainLAB AG, Germany). A C-arm adapter ('Fluoro  
318    3D'; Vector Vision, USA) was used to synchronise intraoperative fluoroscopy  
319    with the 3D CT dataset. This allowed real-time feedback of surgical instrument  
320    placement in relation to the femoral head-neck junction. In 50 cam-type FAI  
321    patients who were divided into a navigated arthroscopy group and a without  
322    navigation group, the navigation software did not increase the rate of operative  
323    success (ROM and non-arthritic hip scores) and surgical time was significantly  
324    longer in the navigated group. This might be partially due to the fact that this  
325    prototype software did not allow preoperative planning and thus did not  
326    highlight the zone of impingement or the amount of resected bone.

327    ● Monahan and Shimada (64) were the first to develop an encoder linkage  
328    system to track surgical instruments during hip arthroscopy. An encoder is a  
329    device which captures tool movement and orientation and it eliminates the  
330    problem of occlusion with standard optical tracking systems. The encoder

linkages are calibrated with preoperative, patient-specific 3D imaging data so the position of the surgical tools can be verified with patient anatomy. In other words, the system displays the real-time surgical instrument position relative to patient anatomy on a screen with a preoperatively generated, patient-specific 3D image. The system incorporates soft tissue as well as bone anatomy and therefore, also serves as a useful aid for safe portal placement.

- Almoussa et al (65) reported that the same shaping accuracy of the femur could be achieved between an experienced surgeon and a novice surgeon when a navigation system was used to treat cam-type FAI. In this study, a preoperative plan was generated from CT scans and the BrainLAB navigation system, and real-time tracking was performed by surgeons using a pointer with marker arrays to ensure resection was performed according to the preoperative plan. The intraoperative images used in this study were dynamic 2D CT scans in sagittal and axial planes of the head-neck junction, rather than a single image of a virtually 3D reconstructed hip. However, the results clearly indicated that navigated arthroscopic surgery based on preoperative imaging and planning may be useful to reduce the steep learning curve of arthroscopic FAI surgery.

- Van Houcke et al (66) reported the outcome of randomised controlled trial

349 which compared the cam resection accuracy via the conventional hip  
350 arthroscopy technique with the navigation technique. Postoperatively, the  
351 mean maximal alpha angle improved significantly in the navigated group  
352 compared with the conventional group, especially in the 12 o' clock position.  
353 However, positioning time and radiation exposure were significantly longer in  
354 the navigated group.

355  
356 Other than those studies shown above, several other studies have reported on  
357 cadaver models. Kendoff et al (67) evaluated an image-based approach in a cadaver  
358 study of six hips and found that a combined CT-fluoroscopy matching navigated  
359 procedure allowed for a reproducible registration process for navigated FAI surgery  
360 at the femoral site, with high precision at the femoral neck and head-neck junction  
361 area with mean deviations below 1 mm. Also, using 12 paired cadaver hips with a  
362 virtual cam lesion, Audenaert et al (68) reported that the estimated accuracy of  
363 image-based registration by means of 3D fluoroscopy had a mean error of 0.8 mm,  
364 while the estimated accuracy of imageless registration in the arthroscopic setting  
365 was poor, with a mean error of 5.6 mm. Ecker et al (69) developed some  
366 computer-assisted planning and navigation software which uses preoperative ROM

373 **5. Future perspectives: robot-assisted surgery**

374 Robot-assisted surgery is definitely the ultimate surgical technology, defined as a  
375 translation from the quantitative assessment produced by navigation to an  
376 automated mechanical surgical action by a robot, i.e. a robotic arm mounted with  
377 surgical instruments that can automate the entire surgical procedure following a  
378 preoperative surgical plan. This provides a greater level of precision, allowing for  
379 unmanned or even remote surgery (9,53,70).

380  
381 Today, the ‘da Vinci’ (Intuitive Surgical, USA) telerobotic platform is the most widely  
382 used robotic surgical system, and its technical specifications have attracted interest.  
383 This system allows the surgeon to sit remotely at a console and control the  
384 movements of robotic arms while viewing the operative site in 3D, and it is being  
385 used in procedures such as hysterectomies (71), prostatectomies (72) and gastric  
386 bypass (73). Currently, robotic hip arthroscopy using this system is feasible only in a  
387 cadaveric model (74). However, remote control of articulated instruments with full  
388 ROM at the tip might enable parts of the hip joint that are inaccessible with rigid  
389 instrumentation to be reached (75,76) and the strong force that the system offers  
390 may be sufficient to work effectively with bony structures and to handle the long

1  
2  
3  
4  
5  
6 391 distance between skin level and the location of surgery. It is assumed that it would  
7  
8  
9 392 be feasible to use this system to perform basic hip arthroscopy due to the basic  
10  
11  
12 393 similarity of instrument design of laparoscopic and arthroscopic surgery (74). The  
13  
14 394 'Tactile Guidance System' (MAKO Surgical, USA), which is currently used to perform  
15  
16  
17 395 partial knee and total hip replacements, has been applied in a study on  
18  
19  
20 396 robotic-assisted femoral osteochondroplasty for FAI, although it was tested in  
21  
22  
23 397 sawbone models only. Nonetheless, this system appears promising, as its precision  
24  
25  
26 398 and accuracy over freehand surgery have been proven in well-constructed  
27  
28  
29 399 experimental models by Cartiaux et al (77).

30  
31 400

32  
33  
34 401 An overall limitation to robotic arthroscopy is the restricted space inside the hip  
35  
36  
37 402 joint. Therefore, future instruments for robotic hip arthroscopy in patients will have  
38  
39  
40 403 to be both small in diameter and flexible. It is clear that robotic hip arthroscopy is at  
41  
42  
43 404 a very early stage at present. However, robotic technology has the potential to  
44  
45  
46 405 revolutionise hip arthroscopy and extend the number of reachable areas of the joint  
47  
48  
49 406 as well as to enable surgeons to perform more complex and precise tasks in the  
50  
51  
52 407 restricted spaces of the hip.

408 **Conclusion**

409 The recent advancement of computer-assisted surgery as a resource for  
410 preoperative planning and intraoperative assistance in hip arthroscopy has provided  
411 more precise surgical planning and the potential for improved operative results.  
412 There have been several studies published describing various technologies which  
413 have shown potential for increasing surgical precision in treating FAI. However, they  
414 are not without limitations, including a steep learning curve, lack of insight into  
415 soft-tissue pathology and restriction to only concentric hips. Future comparative  
416 trials determining the efficacy of computer-assisted hip arthroscopy surgery are  
417 required.
