Blinking is vital to maintain the integrity of the ocular surface and its characteristics such as blink duration and speed can vary significantly, depending on the health of the eyes. The blink is so rapid that special techniques are required to characterize it. In this study, a high-speed camera was used to record and characterize voluntary blinking. The blinking motion of 25 healthy volunteers was recorded at 600 frames per second. Master curves for the palpebral aperture and blinking speed were constructed using palpebral aperture versus time data taken from the high-speed camera recordings, which show that one blink can be divided into four phases; closing, closed, early opening and late opening. Analysis of data from the high-speed camera images was used to calculate the palpebral aperture, peak blinking speed, average blinking speed and duration of voluntary blinking and compare it with data generated by other methods previously used to evaluate voluntary blinking. The advantages of the high-speed camera method over the others are discussed, thereby supporting the high potential usefulness of the method in clinical research.

1. Introduction

A blink is defined as ‘a temporary closure of both eyes, involving movements of the upper and lower eyelids’ [1]. Human adults blink approximately 12 times per minute and one blink lasts about 1/3 s [2]. This natural eye motion is crucial for maintaining the integrity of the ocular surface for the following reasons: blinking (i) lubricates the eye by replenishing the precorneal tear-film, consequently preventing the cornea from dryness and cleaning the corneal surface, (ii) shields the eye from foreign objects such as dirt and dust as well as from the continuous exposure of light, and (iii) relieves early fatigue by allowing the ocular muscles in tension to be reorganized [1–3]. Three different forms of blinking have been described [1]: (i) spontaneous blink, which occurs unconsciously but periodically, (ii) voluntary blink, which occurs intentionally, and (iii) reflex blink, which is triggered by sudden impulse, loud sound or strong light. In this study, we consider voluntary blinks.

Blink characteristics, such as blink amplitude, duration and peak speed vary significantly between healthy and unhealthy eyes [4–7], and hence, an accurate and detailed analysis of a blink is important to detect debilitating conditions early and subsequently provide appropriate treatments. A few methods have been published as a way to investigate the rapid blink movements. The magnetic search coil technique involves taping a coil of copper or stainless steel onto the subject’s upper eyelid then placing the subject in the centre of a weak magnetic field [7–10]. The eyelid position is then monitored by the current generated in the coil in proportion to the angle of the coil relative to the magnetic field, when the eyelid moves over the curved ocular surface. Other methods include home video camera recording [5,6] and tracking the displacement of a reflective marker taped onto a subject’s upper eyelid using infrared cameras.
In this work, a high-speed video camera was used to study the rapid eye motion of the voluntary blink. While most of the literature evaluates blink parameters such as blink duration and speed up to the point when about 97 per cent of the initial palpebral aperture is recovered; in this study, these parameters were evaluated for one complete blink, i.e. when the initial aperture was fully recovered. The results were compared with other reported values, exploring the potential use of the high-speed camera as an accurate and reliable analysing method.

2. Experimental details

Twenty-five healthy volunteers, including 11 males and 14 females participated in this study. Their age ranged from 25 to 63 with the mean of 35 years. Volunteers of oriental origin were excluded from the study. As this was a pilot study of 25 subjects, male and female volunteers were not considered separately. After informing the volunteers about the general purpose of this study, they were comfortably seated on a chair before a high-speed camera, one person at a time. A PHANTOM (v. 7.3, Vision Research Ltd, UK) camera was placed in front of the volunteers at their eye-level. The camera was mounted with a Nikon 24–85 mm F2.8 macro zoom lens and had 800 × 600 pixel resolution. In order to induce blinking, the volunteers were asked to blink as normal as possible after a verbal command. The motion of two voluntary blinks was recorded at a rate of 600 frames per second at 22.6 ± 1.6°C and 28.3 ± 2.2% humidity with natural light.

For each volunteer, the palpebral aperture, which is the vertical distance between the central points of the upper and lower eyelid margins, was measured every 5 ms of the recorded videos, using PHANTOM CINE VIEWER v. 2.14 (Vision Research software). The measurements started from 30 ms prior to the start of a downward movement of the upper eyelid and continued until the initial palpebral aperture value was reached. The second recorded blink was used for this analysis, considering the possibility that the volunteer was more comfortable and relaxed after the first blink. Since the initial palpebral aperture varied from one volunteer to another the measured aperture values for each volunteer were normalized and all the normalized aperture values for the 25 volunteers were averaged at each time point in order to produce a master curve for the palpebral aperture.

For each volunteer, the measured palpebral aperture values were plotted as a function of time and the corresponding blinking speed was determined by calculating the gradient on each consecutive pair of aperture points. When all the blinking speed values were determined for the 25 volunteers, they

were averaged at each time point in order to produce a master curve for blinking speed. The peak speed was taken to be the maximum speed calculated and the average speed was evaluated by dividing the initial palpebral aperture value by the time taken for closing the eye or opening the eye.

3. Results and discussion

The palpebral aperture measurements ranged from 7.4 to 12.8 mm with a mean of 9.8 ± 0.2 mm for all the 25 volunteers. These measurements agree well with Fox [11], who studied the palpebral fissure on 1732 human subjects using a millimetre-ruler and reported that the measurement varied from 7 to 13 mm with 61.7 per cent of the subjects having 9–10 mm aperture values.

All the normalized palpebral aperture values determined from the key frames of high-speed camera videos are shown in figure 1a. The aperture profile could be divided into four phases; (i) closing, (ii) closed, (iii) early opening, and (iv) late opening, depending on the action of the upper eyelid. Some of key frame images of the videos are selected to illustrate each phase (figure 1b). It is noteworthy that others [12,13] divide voluntary blinking into three phases: closing-phase, opening-phase and the inter-phase pause, i.e. the time elapsing between the end of the closing phase and the beginning of the opening phase. The inter-phase pause is important in clinical conditions, such as Parkinson’s disease and atypical Parkinsonism.

During voluntary blinking, all the 25 volunteers fully closed their eyelids, thereby resulting in a brief closed phase with zero aperture values between closing and opening phases. Moreover, unlike the closing phase, the opening phase happened in two stages; early opening with continuous increase in palpebral aperture, corresponding to phase 3 and late opening with intermittent increase in aperture value, corresponding to phase 4. It was observed that about 97 per cent of the initial aperture value was recovered by the end of early opening, phase 3 and the last 3 per cent recovery during the late opening, phase 4. Averaging all the normalized palpebral aperture values and the speed values at each time point resulted in the aperture master curve (figure 2a) and the speed master curve (figure 2b), respectively.

The aperture master curve (figure 2a) shows how the aperture changed over time. It rapidly decreased until it reached approximately 0 for the first 110 ms, then increased rapidly but at a slower rate until 400 ms followed by a much slower increase until it reached its original value. Unlike in the normalized aperture scatter plot (figure 1a), the value never reached zero because of the variation in the timing and the duration of the closed phase between individuals. The speed master curve (figure 2b) exhibits two parabolic curves; one for the closing phase and the other one for the opening phase. The curve demonstrates that the upper eyelid accelerates until reaching its maximum speed then decelerates during the closing or opening action of the eye. The duration of one voluntary blink was determined for each phase (figure 2c).

The closed phase and the late-opening phase had the shortest and the longest duration with 58 ± 4 ms and 273 ± 23 ms, respectively. Moreover, a considerable variation was observed in the late-opening phase duration. Our video analysis showed that one voluntary blink took 572 ± 25 ms although only half

and also the apparent palpebral aperture between the upper weight, which might affect the blink dynamics, is involved obtained from high-speed camera images as no extra eye parameters. A high-speed camera does not require such advantages over the other techniques can make it a more attractive method to analyse eye blinking kinematics.

4. Conclusions

The kinematics of one voluntary eye blink was studied using a high-speed video camera recording at 600 frames per second. The analysis of data recorded showed that one voluntary blink could be divided into four phases; closing phase, closed phase, early-opening phase and late-opening phase identified by the distinctive action of the upper eyelid. One blink took 572 ± 25 ms and was accompanied by asymmetric motion with a much faster closing action compared with the opening action of the eye. The peak speed was determined to be approximately 250 mm s⁻¹ and 160 mm s⁻¹ during the closing and opening phases, respectively, and the closed phase and the late-opening phase took the shortest and longest time, respectively. Comparing the results in this study with other reported findings demonstrates that the high-speed camera technique provides highly reliable results and its advantages over the other techniques can make it a more attractive method to investigate the kinematics of a human blink. This methodology has significant implications for clinical research and practice, providing an experimental platform to examine abnormalities of eyelid movement, such as blepharospasm, thyroid eye disease and myopathic ptosis.

A further study is on-going with a higher number of volunteers to allow for the correlation of blink characteristics with age, gender and other clinical variables. In addition, investigations comparing blink dynamics of healthy and disease states are also on-going.

This study was supported by an EPSRC-UCI Post-doctoral Mobility Award made to the authors.
