ABSTRACT

Background: Fatalistic beliefs may be implicated in longer help-seeking intervals, and consequently, greater risk of advanced stage at cancer diagnosis.

Methods: We examined associations between fatalism and stage at diagnosis in a population-based cohort of 4,319 U.S. patients with newly-diagnosed lung or colorectal cancer participating in the Cancer Care Outcomes and Research Surveillance (CanCORS) study. Fatalistic beliefs were assessed with an established measure. A fatalism score (range 4-16) was created by summing Likert-scale responses to four items. Cancer stage at diagnosis was abstracted from medical records by trained staff. Logistic regression was used to assess the association between fatalism score and advanced stage at diagnosis (IV vs I-III), adjusting for socio-demographic and clinical characteristics.

Results: Overall, 917 (21%) patients had stage IV cancers (lung: 28%, colorectal: 16%). The mean fatalism score was 10.7 (median=11, inter-quartile range 9-12). In adjusted analyses, a higher fatalism score was associated with greater odds of stage IV diagnosis (odds ratio per unit increase in fatalism=1.05, 95% confidence interval 1.02-1.08, $p=0.003$). Patients with the highest fatalism score had an adjusted 8.9% higher frequency of stage IV diagnosis compared with patients with the lowest score (25.4% vs. 16.5%).

Conclusions: In this large and socioeconomically, geographically and ethnically diverse population of patients with lung and colorectal cancer, fatalistic beliefs were associated with higher risk of advanced stage at diagnosis. Longitudinal studies are needed to confirm causation.

Impact: These findings support the value of incorporating information about the curability of early-stage cancers in public education campaigns.

INTRODUCTION

Many cancer patients are diagnosed after a symptomatic presentation, because effective screening tests exist for few cancer sites and participation rates are sub-optimal. For example, in England, more than 90% of all cancer patients are diagnosed following symptomatic presentations (1). As stage at diagnosis is a key determinant of cancer survival, interventions to ensure that symptomatic patients are diagnosed at the earliest possible stage can help to reduce cancer mortality.

Psychosocial factors are important candidates for influencing the length of the period from symptom onset to presentation to a doctor (i.e. the 'patient interval'), and, consequently, the stage at diagnosis (2,3). These factors encompass both cognitive (e.g. awareness of potential associations of symptoms with cancer) and emotional processes (e.g. fear of cancer or embarrassment about symptoms) (4).

Fatalism, whether it relates to a general belief that life events are pre-determined and inevitable, or 'cancer fatalism', defined by Powe as 'the belief that death is inevitable when cancer is present' (5), has been implicated in longer patient intervals in a study of intended help-seeking for breast cancer among asymptomatic women (6). Individuals with more fatalistic beliefs may be both more fearful of a cancer diagnosis and more sceptical about the value of early detection of cancer, and therefore, may delay seeking medical help (7). Several studies have shown that cancer fatalism influences cancer screening uptake (8-10). Direct evidence that fatalism is associated with longer patient intervals in symptomatic patients is limited, although two small single-centre studies including a few hundred patients each and primarily examining the potential determinants of ethnic disparities in cancer outcomes have shown that fatalistic beliefs were associated with advanced stage of diagnosis of breast and lung cancer (11,12). Specifically, an association between endorsing the fatalistic belief '*if it's meant to be, I will stay healthy*' and advanced stage at diagnosis was reported in a sample of 540 women with breast

cancer (11). Further, in 357 patients with lung cancer; there was an independent association between one of three fatalism items (*'bad things are meant to be'*) and advanced stage at diagnosis (12). It is therefore important to extend the focus of prior inquiries about the potential influence of fatalism on stage at diagnosis to larger and more representative samples of patients and encompass cancers other than those previously studied.

Against this background, we hypothesised that cancer patients with higher scores on measures of fatalistic beliefs will be more likely to be diagnosed with cancer at a more advanced stage. We have subsequently examined this hypothesis association in a large population-based survey of newly-diagnosed patients with lung and colorectal cancer.

MATERIALS AND METHODS

Data

Study design and participants: The CanCORS (Cancer Care Outcomes Research and Surveillance) study prospectively enrolled U.S. adults diagnosed with lung or colorectal cancer in 2003-2005 who lived in certain geographic areas (northern California; Los Angeles County, California; North Carolina; Iowa; or Alabama) or received care in one of five health maintenance organizations (HMOs) or fifteen Veterans Affairs medical centers (13,14). Participants were representative of U.S. patients with these cancers (15). Patients were identified within weeks of diagnosis and interviews (with the patient or a surrogate –if the patient was deceased or too ill to participate) conducted approximately 4-6 months after diagnosis. Interviews were conducted by telephone; trained interviewers used computer-assisted telephone interviewing software to navigate complex skip patterns. The study was approved by human subjects committees at all participating institutions.

Among 9,732 CanCORS participants, we studied the 5,453 for whom interviews were conducted with the patients themselves. We then excluded 761 patients who did not respond to all four fatalism items and 373 patients for whom data on stage at diagnosis were not available, resulting in an analysis sample of 4,319 patients (Figure 1).

Data items: A four-item measure assessing general fatalism that had been developed for the Americans' Changing Lives Panel Study (House JS, <http://sodapop.pop.psu.edu/codebooks/hwboa/acl.pdf>) and reported by Jacobson was included in the questionnaire for patients who completed the survey themselves (16). Patients were asked how strongly they agreed or disagreed with the following four statements:

- *When bad things happen, we are not supposed to know why, we are just supposed to accept them.*
- *People die when it is their time to die and nothing can change that.*
- *Everything that happens is a part of God's plan.*
- *If bad things happen, it is because they were meant to be.*

Responses were on a 4-point Likert scale (strongly agree/agree/disagree/strongly disagree; coded as 4, 3, 2, and 1). Jacobson reported results of a factor analysis showing that the four items formed a single scale with high internal reliability ($\text{Alpha}=0.77$) (16), whereas in our analysis sample we have observed a slightly higher value ($\text{Alpha}=0.79$).

Trained abstractors documented stage at diagnosis from medical records based on the criteria of the American Joint Committee on Cancer, 6th edition. Medical records were available for 87% of patients; for other patients, stage data were obtained from cancer registries. Information was also available on cancer site (colorectal or lung), age, sex, race/ethnicity, education, income, marital status, smoking status, count of self-reported co-morbid conditions using the Katz et al. questionnaire (17), self-reported health status a year before the interview (0-100 on a visual analogue scale, 100=perfect health), symptom status at diagnosis (yes/no), and CanCORS study site. Variables were categorized as in Table 1.

Statistical analysis

We compared patients included in the analysis with those excluded (because of not completing an interview themselves, missing responses to all four fatalism items or missing stage at diagnosis, see Figure 1) using logistic regression. After examining Spearman's rank correlation coefficients for pair-wise associations between the four fatalism items, to maximize power, replies to each of the four items were summed and the total score was used in the main analysis; higher scores reflected higher levels of fatalistic beliefs. We categorized advanced stage at diagnosis as stage IV (vs. I-III) and examined crude and adjusted associations between

advanced stage at diagnosis and fatalism using logistic regression. We initially tested whether there was evidence that the association between fatalism and stage at diagnosis varied by cancer site by an interaction term *fatalism*cancer site*, but found no such evidence ($p=0.40$). We therefore included all patients in the same model, adjusting for cancer site, and sex, age, race/ethnicity, education, income, marital status, smoking status, number of co-morbidities, health status a year before interview, and study site. Subsequently, to aid interpretation, we predicted the proportion of patients diagnosed in stage IV for each score of the fatalism scale, by direct standardisation using the regression model (18). The fully observed dataset was used for sample descriptions (Table 1) and 5 imputed datasets, produced through multiple imputation as previously described (19), were used in the logistic regression models, and outputs were combined with the SAS *MIANALYZE* procedure. In the present analysis imputed data only relate to the small proportion of records with missing income (8%) and education, marital and smoking status information (<1% for all three), as all other variables were complete in the analysis sample (a priori restricted to patients with fully observed fatalism and stage at diagnosis, Text Box).

Sensitivity and supplementary analyses: In sensitivity analyses we examined alternative parameterizations of stage at diagnosis and fatalism score, i.e. by categorising advanced stage at diagnosis as stage III/IV vs. I/II; by analysing scores for each fatalism item individually; and by excluding the religious beliefs ('God's plan') item from the total fatalism score. In supplementary analysis we also examined the potential moderating effect of symptom status at diagnosis by repeating the main analysis model, also adjusting for symptom presence at the time of diagnosis (yes/no) and an interaction between symptom presence and fatalism score. Lastly, in a subgroup of patients with known grade and/or lung cancer tumour type (non-small cell / small cell) we have additionally adjusted for tumour grade and/or type.

RESULTS

Sample description. Compared with the final sample (Figure 1), excluded patients (who were predominantly deceased, or too ill to participate at the time of the baseline survey and thus were not asked the fatalism items) were more likely to have had lung than colorectal cancer and to be male, older, Asian and smokers, and with lower educational attainment and income, higher count of comorbidities and more advanced stage at diagnosis ($p < 0.01$ for all, Supplementary Table 1). Among patients included in the analysis the median age was 65 (inter-quartile range: 56-73) and there was a slight preponderance of colorectal cancer and male patients (56% and 55% of the sample, respectively). Just under three quarters of patients were White (72%) and 7%, 13% and 5% were Hispanic, Black and Asian, respectively. Most patients (82%) had symptoms at the time of diagnosis. Further sample details are provided in Table 1.

Stage at diagnosis. Among all patients 1,266 (29%), 849 (20%), 1287 (30%), and 917 (21%) patients were diagnosed in stages I to IV, respectively. The proportion diagnosed with stage IV cancers was greater among patients with lung than colorectal cancer (28% vs 16%, $p < 0.001$).

Fatalism. The mean fatalism score was 10.7 (median score: 11, inter-quartile range: 9-12). Responses to the four individual items were moderately correlated (pair-wise Spearman rank correlation coefficients range: 0.34 to 0.55, $p < 0.001$ for all). There were differences in fatalism scores by race/ethnicity, with mean scores of 10.5 for White, and 11.3, 11.3 and 10.9 for Hispanic, Black and Asian patients, respectively ($p < 0.001$). On average, women had higher mean fatalism scores than men (10.9 vs 10.5, $p < 0.001$) and the same was true for current smokers compared with former smokers and non-smokers (11.0, 10.6, 10.8 respectively, $p < 0.001$). Patients with lower educational attainment had higher fatalism scores than patients with higher education (11.8, 10.9 and 9.5 respectively for non-high school graduates, high school graduates and college graduates, $p < 0.001$). Patients with lower income also had higher fatalism scores than patients with higher income (11.3 and 9.8 respectively for patients with

annual income <\$20,000 and >60,000, $p<0.001$). There were no notable associations of fatalism with count of comorbid conditions, symptomatic detection status, or cancer site.

Crude associations. In crude analysis (logistic regression), higher fatalism scores were associated with advanced stage at diagnosis (odds ratio per unit increase in fatalism=1.05, 95% confidence interval (CI): 1.02-1.08, $p=0.001$). Other factors associated with stage IV diagnosis included lung cancer, younger age, lower count of co-morbidities, being a current smoker, and symptomatic detection ($p<0.01$ for all, Table 2).

Adjusted associations. Adjusted analysis (logistic regression) revealed a very similar association between fatalism and stage IV diagnosis (odds ratio per unit increase in fatalism=1.05, 95% CI: 1.02-1.08, $p=0.003$, Table 2). Patients with the highest fatalism score (16) had an odds ratio of 1.77 (95% CI 1.21-2.57) for advanced stage at diagnosis compared with those with the lowest score (4) – equivalent to an absolute adjusted difference of 8.9% in the proportion of patients diagnosed with stage IV cancers (Table 3). Similarly, patients with the highest score (16) had an odds ratio of 1.34 (95% CI 1.10-1.60) for stage IV diagnosis compared with those in mid-scale (10) – equivalent to 4.7% increase in the proportion of patients diagnosed with stage IV cancers. There was also evidence that lung cancer, male sex, younger age, and lower count of co-morbid conditions were associated with higher odds of stage IV diagnosis ($p<0.01$ for all, Table 2).

Sensitivity analysis. When we examined the association of fatalism with stage III/IV diagnosis, the direction of association remained but its strength was attenuated, such that there was only weak evidence for an association (OR=1.03, 95% CI: 1.00-1.05, $p=0.055$, Supplementary Table 2). When running logistic regression models that included each individual fatalism item separately instead of the total score (four separate models) the observed findings were concordant with those of the main analysis, with respective odds ratio >1.0 and some significant associations. Repeating the analysis using a total score but excluding the ‘God’s plan’ individual

item also produced concordant results (OR=1.06, 95% CI: 1.02 to 1.10, p=0.004). Similarly, inclusion of symptomatic detection status and an interaction variable *symptomatic detection*fatalism score* produced concordant findings to those observed in the main analysis with no evidence for an interaction (p=0.68). Adjustment for tumour grade and/or lung cancer type made no material difference to the findings of the main analysis model.

DISCUSSION

In a large population based survey of patients with lung and colorectal cancer, we observed an independent association between higher fatalism scores and advanced stage at diagnosis of lung and colorectal cancer. Sensitivity analyses provided concordant findings.

Although previous research has documented associations between fatalism and lower participation in cancer screening (8-10), evidence linking fatalism with clinical outcomes such as stage at diagnosis is limited. Our inquiry is methodologically similar to two previous studies, and a smaller qualitative study of breast cancer patients (11,12,20), but has a substantially larger and socio-demographically and geographically more diverse sample that includes patients with both lung and colorectal cancer.

Powe and Finnie suggest that the two factors that shape fatalism are *angst*, defined as the perceived collapse of meaning in the presence of despair about the future, and *nihilism*, defined as the lived experiences of coping with feelings of meaningless, hopelessness, and despair (5). Accordingly, cancer fatalism takes shape as individuals experience others being diagnosed with cancer at an advanced stage, leading to poor outcomes and death. This can lead to scepticism about the value of cancer screening or prompt symptomatic presentation, leading to prolonged intervals to presentation and increasing the risk of advanced stage at diagnosis (21). In addition, cultural or religious values emphasising acceptance may accentuate fatalistic attitudes among some groups (22). Modifying entrenched fatalistic beliefs is not likely to be easy, but evidence that an understanding of the value of prevention or early diagnosis can be held in parallel with fatalism suggests that exposure to culturally appropriate information on the value of early detection might be beneficial (23). If fatalistic beliefs can be modified, campaigns to promote symptom awareness are also likely to contribute to more rapid symptomatic presentation (24). In a recent development of a new scale, Shen et al. propose that fatalism is a multidimensional construct, encompassing 'predestination', 'luck' and 'pessimism' (25). The Fatalism scale used in the present study more closely resembles the predestination dimension, and it will be important in future work

to examine the differential effects of these three elements on screening and help-seeking behaviours.

Strengths of our study include its relatively large and diverse patient population and high data quality, including information on stage at diagnosis abstracted from medical records and the use of validated instruments for assessing fatalism. We were also able to adjust our analysis for a large number of potential confounders, including age, sex, race/ethnicity, education, income, co-morbidity, smoking status and prior health status.

Our study has two principal limitations. First, our analysis included only patients who were alive and able to complete the baseline survey, resulting in relative under-representation of older and more co-morbid patients and those with more advanced stage at diagnosis (Supplementary Table 1). However, sample attrition and non-response patterns are a necessary but not sufficient condition for non-response bias in estimates of associations. After appropriate adjustment for case-mix the effect of such bias in surveys with an appropriately defined sampling frame is small (26,27). Achieving more representative patient samples might be possible if interviews are conducted sooner after diagnosis; however, this is rarely feasible in large population-based studies of cancer patients.

Second, as for any cross-sectional study, the causal direction of the observed association cannot be proven. Fatalism could lead to advanced stage at diagnosis, but it is also possible that advanced stage at diagnosis could lead to higher fatalism scores, although Powe has reported unpublished data indicating that cancer fatalism has declined from pre- to post-diagnosis (28). Nevertheless, a causal association of fatalism with advanced stage at diagnosis is plausible. If people believe that cancer is inevitably fatal, then they might delay or avoid seeking medical help after symptom onset or participation in cancer screening, and thus have a higher risk of advanced cancer at diagnosis. Although we did not observe statistically significant differences in fatalism scores based on presence or absence of symptoms, patients may have differed in how long they waited to seek care after developing

symptoms. Other studies of asymptomatic individuals have documented associations between fatalism and both intended help-seeking and participation in cancer screening, further supporting a causal effect of fatalism on the length of the patient interval and stage at diagnosis (6-10). Prospective cohort studies involving fatalism measurement in individuals who are free of cancer at study entry would be ideal, but would require large populations and adequate follow-up to achieve sufficient numbers of cancer cases. Critically, new prospective studies would be associated with ethical challenges (i.e. leaving fatalistic beliefs about cancer curability unchallenged during follow-up could be considered unethical). This may explain why the few previous studies have also measured fatalism after diagnosis (11,12).

When fatalism items form part of surveys of patients after a cancer diagnosis, there may be ethical concerns about use of cancer-specific fatalism items, and this was the rationale for using a general fatalism item in the CanCORS study. A qualitative study confirmed low acceptability of cancer fatalism questions among recently diagnosed breast cancer patients (29). General (as opposed to cancer-specific) fatalism items may have both merits (e.g. less likely to be prone to bias resulting from knowledge of cancer diagnosis) and limitations (it makes the argument for public health interventions aimed at reducing 'cancer fatalism' less direct). Subject to research ethics considerations, future surveys of cancer patients may be able to investigate differences in results from use of general and cancer-specific fatalism items.

In conclusion, we identified an association between fatalism and advanced stage at diagnosis for patients with newly-diagnosed lung and colorectal cancer, most of whom had presented with symptoms. The consistency of these findings with those from other qualitative and quantitative studies, the plausibility of the association and its large size suggest that the findings should be considered in the context of public health policy initiatives and education campaigns designed to shorten the patient interval of newly diagnosed cancer cases (30,31). Traditionally such strategies have focused on cognitive

aspects (i.e. 'awareness' of cancer symptoms) but including 'anti-fatalism' components could have a powerful impact. Such approaches may include factual information about the high probability of long-term survival when the diagnosis occurs at a non-advanced stage and the availability of effective treatments that offer good health-related quality of life.

	No	11.6	-					
Health status a year before interview (0-100)			1.00	1.00-1.01	0.028	1.00	1.00-1.01	0.223

*From univariable or multivariable regression, as applicable. Multivariable regression models adjusted for all variables in the table except symptom status at diagnosis.

Table 3. Proportion of patients diagnosed with stage IV cancers (crude and case-mix adjusted)

Fatalism score	n	Observed (crude) rate	Adjusted percentage*
4	98	18.4%	16.5%
5	47	14.9%	17.2%
6	108	18.5%	17.8%
7	151	17.9%	18.5%
8	443	16.7%	19.2%
9	505	21.4%	19.9%
10	544	23.7%	20.7%
11	664	21.8%	21.4%
12	923	19.2%	22.2%
13	322	27.0%	23.0%
14	179	16.2%	23.8%
15	133	27.8%	24.6%
16	202	29.2%	25.4%

*Adjusted proportions calculated from the logistic regression model – this is the expected percentage that would have been observed if the case-mix of patients in each fatalism score category was the same as in the total sample
