We present new experiments of the motion of a turbulent gravity current produced by the rapid release of a finite volume of dense aqueous solution from a lock of length $L$ into a channel $x > 0$ filled with a finite depth, $H$, of fresh water. Using light attenuation we measure the mixing and evolving density of the flow, and using dye studies, we follow the motion of the current and the ambient fluid. After the fluid has slumped to the base of the tank, there are two phases of the flow. When the front of the current, $x_n$, is within the region $2L < x_n < 7L$, the fluid in the head of the current retains its original density and the flow travels with a constant speed. We find that about $0.75(\pm0.05)$ of the ambient fluid displaced by the head mixes with the fluid in the head. The mixture rises over the head and feeds a growing stratified tail region of the flow. Dye studies show that fluid with the original density continues to reach the front of the current, at a speed which we estimate to be about $1.35 \pm 0.05$ times that of the front, consistent with data of Berson (1958) and Kneller et al. (1999). This speed is similar to that of the ‘bore’, the trailing edge of the original lock gate fluid, as described by Rottman and Simpson (1983). The continual mixing at the front leads to a gradual decrease of the mass of unmixed original lock gate fluid. Eventually, when the nose extends beyond $x_n \approx 7L$, the majority of the lock gate fluid has been diluted through the mixing. As the current continues, it adjusts to a second regime in which the position of the head increases with time as $x_n \approx 1.7B^{1/3}t^{2/3}$, where $B$ is the total buoyancy of the flow per unit width across the channel, while the depth averaged reduced gravity in the head decreases through mixing with the ambient fluid according to the relation $g'_n \approx 4.6H^{-1}B^{2/3}t^{-2/3}$. Measurements also show that the depth of the head $h_n(t)$ is approximately constant, $h_n \sim 0.38H$, and the reduced gravity decreases with height above the base of the current and with distance behind the front of the flow. Using the depth averaged shallow-water equations, we derive a new class of self-similar solution which models the lateral structure of the flow by assuming the ambient fluid is entrained into the current in the head of the flow. By comparison with our data, we estimate that a fraction $0.69 \pm 0.06$ of the ambient fluid displaced by the head of the current is mixed into the flow in this approximately self-similar regime, and the front of the current has a Froude number $0.9 \pm 0.05$. We discuss the implications of our results for the evolution of the buoyancy in a gravity current as a function of the distance from the source.

1. Introduction

Turbulent gravity currents are produced when a finite volume of dense fluid is rapidly released from a source above a horizontal boundary into an environment of lower density. The dense fluid propagates horizontally under gravity along the lower boundary of the flow domain by displacing the original fluid in place. Owing to the considerable importance of gravity currents in many geophysical and environmental flows, their dynamics have been studied in some detail, using a combination of laboratory experiments and mathematical models. Important applications have been described by many authors (Simpson (1997)) and, amongst other phenomena, include: the dynamics of cold fronts; the spread of dense gas following release from a vessel, for example in an explosion; the dynamics of submarine turbidites, which are dilute particle-laden flows (Buckee & Kneller 2000); and volcanic ash flows (Sparks et al. 1997). In the context of many of the above flows, the propagation speed and the density structure of the flow as it spreads from the source are of considerable interest. The key advance in this work is a quantitative assessment of the dilution of a two-dimensional gravity current by mixing of the fluid originally ahead of the current and displaced by the current: to this end, we combine new laboratory experiments with a new theoretical model.

1.1. Historical perspective

One of the first analyses of the dynamics of a gravity current was presented by von Karman (1940) in which the critical role of the head of the flow was recognised, and in which potential theory was used to predict that the front of the current makes an angle of 60° with the ground. In this analysis, mixing between the fluid in the head and the ambient was neglected. However, subsequently, Prandtl (1952), in discussing the advance of a mass of cold air along the ground, proposed that there would be mixing between the head of the cold current and the ambient fluid, and this led him to infer that the speed of the fluid in the current would exceed the speed of the head (figure 1a). This work stimulated many measurements in the atmosphere (e.g. (Berson 1958)) which suggested that the speed of the front was in the range 0.5-0.65 times the speed of the fluid supplying the cold front.

Meanwhile, in a highly influential paper, Brooke-Benjamin (1968) introduced a two layer model for the dynamics of a two-dimensional gravity current and the ambient fluid through which it propagates, using an integral approach to describe the conservation of momentum flux across the head of the flow. This model diverged from the picture proposed by Prandtl, in that there was no account of the mixing or recirculation in the head of the flow, and the fluid speed was assumed to equal the speed of the flow front (figure 1b). Many studies have built from the pioneering contribution of Benjamin, focussing on modelling the location of the head of the current as a function of time. For currents which remain of high Reynolds number sufficiently far from the source, it has been shown that there is an initial near-source phase of constant speed, followed by a phase of slowly waning speed (Chen 1980; Rottman & Simpson 1983; Marino et al. 2005; Huppert & Simpson 1980; Hoult 1972; Bonnecaze et al. 1993). Rottman and Simpson (1983) suggested that during the initial phase of constant speed, a bore propagates from the back of the gravity current, eventually catching the front of the flow; they developed a two-layer shallow water model, neglecting any effects of mixing and presented some experiments to illustrate the phenomenon. In the experiments, a shadowgraph identified a region of strong stratification at the rear of the head, which propagated towards the front of the current, and this was described as the bore. In the subsequent waning phase, experimental data has shown that the front of the gravity current follows a power-law distance-time relationship of the form \( x_n(t) \sim \lambda B^{1/3} t^{2/3} \) where \( B \) is the total buoyancy,
given by the product of the volume of fluid behind the lock gate and the reduced gravity of the fluid per unit width of the two-dimensional channel, and \( t \) is the time after release of the fluid, while \( \lambda \) is a constant. These observations have led to a series of models for the flow, based on shallow water theory of a single or two layer flow (Hoult, 1972; Chen, 1980, Bonnecaze et al., 1993). The models have been shown to admit self-similar solutions in which it is assumed that there is no mixing, so that the volume of the current is constant. As a result, the solutions predict that the depth of the flow decreases as the lateral extent of the flow increases, while the buoyancy of the current remains a constant. In these models, it has been assumed that at the front of flow the fluid speed equals the speed of advance of the current, \( u = \frac{dx}{dt} \), and that the speed of the fluid is given by \( u = Fr(g'h)^{1/2} \) where \( Fr \) is the Froude number, and \( g'h \) is the product of the reduced gravity, \( g' \), and the depth of the flow, \( h \), at the front.

However, following the early work of Prandtl (1952), there have been several key experiments which demonstrate that the fluid in a gravity current mixes with the ambient fluid, leading to considerable dilution and an increase in the volume of the flow (Hallworth et al. 1993, 1996; Hacker et al. 1996; Marino et al. 2005). Hacker et al. (1996) and later Marino et al. (2005) used a light attenuation technique to measure the dilution of the flow, and presented some fascinating data which illustrates that the flow develops a complex stratified structure as it mixes with the ambient fluid. Marino et al. (2005) focussed on measuring the effective local Froude number for the speed of the flow front, based on experimental measurements of both \( g' \) and \( h \) near the front of the flow. Hallworth et al. (1993, 1996) used a pH indicator together with an acid and base in the current and ambient fluid, to measure the mixing in the head of the current. By varying the initial pH of the current and ambient fluids in successive, otherwise identical experiments, they were able to produce estimates of the degree of mixing in the head of the flow as a function of the distance from the source. Based on their data, they proposed that some of the ambient fluid ahead of the current is mixed into the head, and that in turn, the head then emits some of the mixed fluid to form a wake. Hallworth et al. (1993, 1996) then developed an integral model for the volume and buoyancy of the head. The model did not examine the evolution of the wake, but the reduced gravity of the fluid being detrained from the head into the wake is predicted to become progressively smaller as the current advances and the reduced gravity of the head falls. They also reported that the head of the current remains undiluted for some distance from the source, and that only then does it begin to mix and dilute. The transition from a current in which the reduced gravity in the head equals that of the fluid originally behind the lock gate to one in which the reduced gravity of the head progressively decreases with distance from the source was also reported in the data of Marino et al. (2005), with the transition occurring in the region 8-10 lock lengths ahead of the source. In his review paper, Huppert (2006) discussed the observation of a density stratified current reported by Hacker et al. (1996) and contrasted this with the data of Hallworth et al. (1993, 1996), inferring that the processes of mixing and dilution remain an unresolved feature of gravity current dynamics. To help interpret controls on the mixing in the near source region, Fragoso et al. (2013) quantified the evolution of the available potential energy of the current (Winters et al. 1995) and other researchers have carried out very high resolution numerical simulations (Hartel et al. 2000).

Following a different approach, (McElwaine 2005) has developed some new solutions, using potential theory, for an idealised non-mixing gravity current, building on the classical work of von Karman (1940) and Yih (1966). He predicts that there is a vortex with anticlockwise circulation in the head of a flow propagating to the right. This has some qualitative similarities with measurements of the velocity within gravity currents. For
example (Thomas et al. 2003) presented some particle image velocimetry measurements which reveal a circulation near the top of the head of the current, but also a second circulation near the base of the current. Kneller et al. (1999) also presented data on the vertical velocity profile in a gravity current, which identified that there is a significant vertical shear in the flow, with a velocity maximum in the lower half of the current and a velocity reversal near the top of the flow. As well as measurements of the velocity profile, observations of the head of a gravity current include descriptions of cleft and lobe structures (Simpson (1997); Simpson & Britter (1979)) which lead to the engulfment of ambient fluid and are associated with the detailed process of mixing in the head region of the current. This mixing provides a critical connection between the head and tail of the current.

As mentioned above, there are a range of so-called ‘box-models’, and also self-similar solutions of shallow water theory (eg. Hoult, 1972; Chen, 1980; Bonnecaze et al., 1993) which have been proposed to describe the motion of gravity currents produced from the release of a finite volume of fluid behind a lock. However, the majority of these neglect the mixing with ambient fluid, but subsequent experimental observations (Marino et al. 2005; Hallworth et al. 1993, 1996; this paper) have suggested that (i) all fluid in the current has become diluted once the flow has travelled of order 7 – 10 lock lengths and (ii) the volume of the current increases by a factor of 3 – 4 over the first 8 – 10 lock lengths (section 3, fig 9a). A more recent, purely theoretical model has hypothesized that mixing in a gravity current occurs on the upper surface of the flow based on the value of the Richardson number on the upper surface of the flow ((Johnson & Hogg 2013)). However, this model predicts that the reduced gravity of the current decreases downstream, in contrast to the experimental data reported in Marino et al. (2005) and herein, for currents which have propagated up to 25 lock lengths downstream of the source. Experimental data shows that the reduced gravity has a maximum at the head
of the current, and smoothly decreases upstream towards the lock gate. This suggests
that, in detail, there is a different process governing the mixing and evolution of density
in the flow, at least in a region up to 25 lock lengths beyond the original lock gate.

1.2. Modelling the mixing

In this paper we investigate the process of mixing in a gravity current, focussing on the
region up to about 25 lock lengths downstream of the source. Using light attenuation
techniques, as well as video analysis, we present new experimental data concerning the
evolution of the density, speed and depth of our experimental gravity currents as they
spread along a flume. We also report a series of new experimental observations of the
mixing within the gravity current, in which we use dye as a tracer to illustrate the
flow pattern and process of mixing. Building from these observations, we develop a new
depth averaged model for the dynamics of a two-dimensional gravity current, produced
from the release of a finite volume of fluid, as it propagates along a flume. We combine
our observations with the model to develop some new self-similar solutions for the flow.
Following a description of the experimental technique, we have divided the presentation
into two parts.

First, we describe the initial adjustment phase of the flow, following the release of a
finite volume of fluid of uniform density from behind the lock gate. As the head advances
up to the point \( x_n = 7L \), we find that the leading part of the head is composed of original
lock gate fluid and has a nearly constant depth, so that it advances with a constant speed.
During this phase, we establish that a circulation develops as fluid at the front of the
current mixes with some of the ambient fluid displaced by the current. The mixed fluid
rises over the head, and supplies a dilute wake behind the flow (figure 1c). Our dye studies
suggest that, during this phase, the original lock gate fluid advances towards the nose
of the flow with a speed of about 1.35 times the speed of the nose. This is comparable
to the speed of the 'bore' identified by Rottman and Simpson (1983), and we find that
this bore catches the front of the flow in the region \( 7L < x_n < 8L \). By measuring the
change of volume of the current as a function of time, we also estimate that during this
adjustment regime a fraction \( 0.75 \pm 0.05 \) of the ambient fluid displaced by the advancing
current becomes mixed into the current.

In section 4, we explore the dynamics after the initial mixing regime, once the gravity
current has become vertically and laterally stratified in density. We find that it rapidly
adjusts towards a self-similar regime, in which the recirculating flow continues to supply
relatively dense fluid into the head, where it mixes with the ambient fluid displaced by the
flow, and then circulates back over the head to feed the tail of the current. In this regime,
we show that the position of the head of the current increases with time as \( x_n \sim B^{1/3}t^{2/3} \),
where \( B \) is the total buoyancy of the current per unit width of the lock gate, and \( t \) is time.
In addition, we find that the reduced gravity of the head scales as \( g'(x_n) \sim B^{2/3}t^{-2/3}H^{-1} \),
while the depth of the head has near constant value \( h(x_n) \approx 0.38H \), with \( H \) the total
depth of the fluid in the flume. We test this picture by measuring the depth and reduced
gravity of the current as it propagates along the flume. We also show experimentally
that, at a given time, the reduced gravity increases as we move from the tail into the
head of the current.

Motivated by these experimental results, we develop a new class of self-similar solutions
for the motion of an idealised gravity current based on the depth averaged equations for
the flow. The novelty of our model is two-fold. First, the velocity and reduced gravity of
the current are vertically stratified, both being greater in the lower half of the current. As
a result, the vertical average of the product of the speed and the reduced gravity exceeds
the product of the vertically averaged speed and the vertically averaged reduced gravity.
In the laterally stratified flow, this results in the continual transport of the reduced gravity towards the head of the flow, and hence, at a given time, there is a gradual increase in the vertically averaged reduced gravity if one moves downstream through the current, i.e. towards the front of the current from the lock gate. Second, based on our dye studies, and in accord with velocity profiles measured by Kneller et al. (1999), we model the entrainment and mixing of ambient fluid into the flow as occurring primarily in the head region of the flow. We quantify the rate of entrainment in terms of the fraction $E$ of the fluid directly ahead of the current which is mixed into the current as it is displaced by the current. We compare the ensuing self-similar solutions for the shape and structure of the current with our experimental data, and determine the best fit coefficients for the above scaling laws controlling the position and reduced gravity of the head of the flow. Finally we draw some conclusions, and discuss the implications of our results more broadly.

We note at this stage that our work relates to gravity currents released into a two-dimensional flume of finite depth. Our experiments span a range of initial volume and reduced gravity, leading to flows with Reynolds number in the range 3000-40,000 (see later, figure 10d). This range overlaps with the majority of published experimental data on gravity currents (e.g. Rottman and Simpson, 1983, Marino et al., 2005, Fragoso et al., 2013, Hallworth et al., 1993, Bonnecaze et al., 1993). We have also explored the dynamics as the aspect ratio of the lock gate ranges from $H/L = 0.25 - 3.0$. There is clearly a much broader range of experiments which could be conducted, and in which many other properties are changed. However, the present body of experiments forms a coherent description of the dynamics of a gravity current produced by a finite release of buoyancy into a fluid of finite depth, and in which we account for the displacement and mixing of the ambient fluid originally ahead of the current.

2. Experimental Method

A series of turbulent laboratory gravity currents were generated through the release of a finite volume of aqueous salt solution into a 3m long perspex tank of width 15cm and depth 36cm. The details of the parameters for each experiment are shown in Table 1, including the depth of the fluid, $H$, the length behind the lock gate, $L$, and the aspect ratio $AR$ of the source, $H/L$, as well as the reduced gravity associated with the salinity, $g'$. In many of the experiments, the aqueous solution was initially dyed with a known mass of red TRS food dye, and the tank was back-lit using a matrix LED light panel (W&Co Displays and Signs). In order to measure the dilution of the current associated with the mixing, solutions with different concentration of dye were placed in the experimental tank, in sequence, and the red-green-blue (RGB) light intensity was recorded for each such solution using a Nikon D90 RGB DSLR camera. The images were analysed using a MATLAB script in order to generate a calibration curve relating light intensity and salinity, averaged along the path of each light ray, following an approach analogous to Hacker et al. (1996); Fragoso et al. (2013) and van Sommeren et al. (2012). The experimental images can then be analysed to determine the distribution of salt within the tank. The total mass of salt as measured during an experiment typically varied by 2-5 wt%. The camera was set to take between 2 and 4 frames per second with shutter speed 1/100, aperture F8 and ISO 800. The precise timing of the images was checked carefully in a control experiment. The camera recorded 14 pixels per cm in the vertical and horizontal directions throughout the flow domain.
3. Adjustment from a homogeneous to a stratified flow

In presenting our experimental results of the initial adjustment, we normalize horizontal distance $x$ and vertical distance $y$ with the lock-length, $L$, leading to dimensionless lengths $\hat{x}, \hat{y}$, current depth $\hat{h}$ and time $\hat{t}$ defined as

$$
\hat{x} = \frac{x}{L}, \quad \hat{y} = \frac{y}{L}, \quad \hat{h} = \frac{h}{H}, \quad \hat{t} = \frac{t}{\tau}.
$$

where the time-scale $\tau = (L/g'_o)^{1/2}$ with $g'_o$ the initial reduced gravity of the dense fluid behind the lock gate. The salt concentration $C$ is scaled with the initial salt concentration $C_o$, leading to the dimensionless salt concentration $\hat{c} = C/C_o$. Assuming the salt concentration is small, the reduced gravity varies linearly with the salt concentration so that $g'(\hat{c}) = g'_o \hat{c}$. In this limit, the concentration of salt and the reduced gravity are directly equivalent.

3.1. Evolution of the reduced gravity, depth and position of the current

Figure 2 (panels a-j) illustrates the time evolution of the gravity current for experiment I1 (Table 1). The false colour images correspond to the concentration of the fluid in the tank at 10 times after release of the lock gate. The current initially adjusts after

Table 1. Table of experiments illustrating range of aspect ratio and volume. a. light attenuation experiment; b. dye injected into head of the flow; c. dye injected into the ambient fluid.
removing the lock gate, and as the front, located at position $\hat{x} = \hat{x}_n(t)$ advances through the region $2 < \hat{x}_n < 7$, the current has a nearly constant density head region, followed by a growing tail, in which the density decreases with distance behind the front and with height above the base of the current. As the current continues to lay down a dilute tail, the region of near constant density at the front of the flow becomes progressively smaller, and eventually dissipates as it advances beyond the point $\hat{x}_n = 7$ (panels c-d). As the flow continues the buoyancy everywhere in the flow becomes progressively smaller with time, with the buoyancy increasing from the lock gate towards the head.

To help visualise the changes in the flow as it advances along the tank, in figure 3 we present a false-colour image of the vertically averaged current concentration as a function of position and time for experiment II. This image illustrates how the speed of the head is constant up to the point $\hat{x}_n \approx 7$, and in this near lock gate region, the fluid directly behind the front of the current has reduced gravity equal to that of the fluid behind the lock gate. However, downstream of this point, the speed and the reduced gravity of the head gradually decrease with distance. The figure also shows how an ever growing tail develops in which the concentration gradually increases from the lock gate towards the
Figure 3. Evolution of the depth averaged concentration of the current as a function of position and time. The horizontal axis represents position ahead of the lock and the vertical axis is time. The colours represent the depth averaged salt concentration of the gravity current, with the legend illustrating a linear scale from 0 to 50 g/l where 50 g/l corresponds to the concentration of salt in the original fluid behind the lock gate. The figure illustrates how the concentration varies with position and with time in the current and shows that the head of the flow becomes progressively more dilute, with the initial buoyancy in the flow being dispersed from the lock gate up to the head of the flow.

Using the new data, in figure 4 we show the dimensionless position of the front of the gravity current, $\hat{x}_n(t)$, as a function of time, for experiments A-G, I1, and O-P (Table 1). The data collapse to a universal curve, labelled ‘front’, independent of aspect ratio, buoyancy and current volume (cf. Huppert and Simpson, 1980). Our images also show that as we move back into the current from the head, the region of fluid whose reduced gravity equals that of the fluid behind the lock gate initially deepens and then thins out (figure 2). To illustrate how the size of this region evolves in time, we first measure the surface in the fluid where the reduced gravity is a fraction 0.95 of the original reduced gravity of the fluid behind the lock gate. We then find the depth of the current at which the depth averaged concentration is a maximum, $h_{cm}$ say, and we draw a horizontal line at a height $0.3h_{cm}$ above the lower boundary. Finally, moving forward along this line from the origin, we measure the location at which this line first meets the surface on which the reduced gravity equals 0.95 of the original lock gate fluid. Measurements of this location, as a function of time, for experiments A-G, I1 and O-P are plotted in figure 4a. Again, although there is some scatter, the data seem to collapse to a universal curve, labelled ‘rear’ for $x_n > 2x_0$. We note that near the origin, several waves of dense fluid may form as the flow slumps from the lock gate to form the current (figure 2, panels a,b). In this region, $\hat{x}_n < 2$, depending on the variations from experiment to experiment, the above measurement may select a transient wave behind the main head as corresponding...
Figure 4. a. Characteristic diagram illustrating the dimensionless position of the front and rear of the head of the current, as a function of dimensionless time, for experiments A-G, H and O-P. The rear is defined as the horizontal position on the fluid surface $\hat{c} = 0.95$ at which the height equals $0.3h_{cm}$, where $h_{cm}$ is the depth of the current where the depth-averaged concentration is a maximum (see figure 1). Symbols for the different experiments are: A red diamonds, B red triangles, C blue triangles, D grey circles, E purple diamonds, F grey squares, G green triangles, H1 blue circles, O blue squares, P orange circles. (b) Variation of the vertically averaged dimensionless salt concentration, $\tilde{c}$, as a function of the distance along the current. Data are shown at a series of times as the current advances along the tank. In (b), corresponding to experiment C (Table 1), the first three profiles have nearly constant concentration at the front of the flow ($\tilde{x}_n < 7$), while in the subsequent profiles, corresponding to more distal positions of the front of the flow; the salt concentration of the head region gradually decreases. (c) Variation of the depth of the current as a function of position in the current for the same experiment as in panel b. Panels b and c are typical of all the experiments.

to the rear of the current. However, as the current then self-organises into the familiar head and wake structure, the trailing waves wane and so further from the source, $\tilde{x}_n > 2$, this measurement of the rear surface of the head collapses towards a universal line for all our experiments, as shown with black dashes in figure 4a. We note that for some experiments, there may be a small increase in the position of the rear surface of the
current near $\hat{x}_n = 2$ as a result of our measurement method; the method may detect a point on one of the decaying waves for $\hat{x}_n < 2$ but, as this decays, it then detects the rear of the main head of the current further downstream. If a higher horizontal line is chosen, we see some scatter in the data owing to the turbulent fluctuations which develop and drive the mixing just behind the point $x(h_{cm})$ (see later), and so in the present work we show the intersection of the line $y = 0.3h_{cm}$ with the contour on which the reduced gravity equals 0.95 of the original value.

We note that in the original work of Rottman and Simpson (1983), data was presented showing the location of the front of the gravity current and of a 'bore' which was described as advancing from the back wall of the tank towards the front of the head. This was apparently measured from shadowgraph data. The data in figure 8 of Rottman and Simpson (1983) represents the location of what they described as a 'bore'. This data very nearly maps onto the curve we describe as 'rear', although the 'bore' tends to spread a little more slowly downstream, perhaps a result of the shadowgraph picking up the density gradient which develops behind the head (figure 2). In summary, we find that in the dimensionless $(\hat{x}, \hat{t})$ space, the leading edge follows the relation $\hat{x} = (0.45\pm 0.03)\hat{t} + 1.4$ while the trailing edge follows the relation $\hat{x} = (0.63\pm 0.03)\hat{t} - 1.3$. As these two curves converge, the region between the curves, in which the density equals the original density of the fluid behind the lock gate, dissipates. Subsequently, the fluid everywhere in the current has a smaller density than the original fluid released from the lock (figure 2, 3).

In figure 4, panel (b) we show how the vertically averaged concentration (or, equivalently, reduced gravity) of the current varies with position in the current. Curves are shown for a series of times as the current advances from the source. The experiment corresponds to a current with initial aspect ratio 1 (expt C, Table 1). For convenience, in this figure, we have defined the vertically averaged concentration as

$$\bar{c} = \frac{\hat{s}(\hat{x}, \hat{t})}{\hat{h}(\hat{x}, \hat{t})} \tag{2}$$

where $\hat{s}(\hat{x}, \hat{t})$ represents the total dimensionless salt content of the current per unit distance along the boundary

$$\hat{s}(\hat{x}, \hat{t}) = \int_0^{\hat{h}(\hat{x}, \hat{t})} \hat{c}(\hat{x}, \hat{y}) d\hat{y} \tag{3}$$

and where $\hat{h}(\hat{x}, \hat{t})$ represents the maximum dimensionless height at which a concentration signal above background noise is detected. In the present experiments, $\hat{h}(\hat{x}, \hat{t})$ is taken to be the height at which the dye concentration falls below 4% of the initial concentration behind the lock gate. Figures 4(b) illustrates that the dimensionless average concentration in the head of the flow remains approximately constant until $\hat{x}_n \approx 7$ beyond which it gradually decreases. Note that the vertically averaged concentration includes the lower part of the current composed of original lock gate fluid, and the upper part of the flow composed of mixed fluid (figure 2).

In figure 4(c) we show profiles of the current depth as a function of position within the current, with the profiles taken at times corresponding to the concentration profiles shown in figure 4(b). It is seen that the depth at the nose of the current is approximately uniform, in the region $2 < \hat{x}_n < 7$. However, as the head advances further downstream, the depth adjusts to what appears to be another fixed value $\hat{h}_n \approx 0.38$ (see section 4). The combination of constant depth and reduced gravity at the head enables the flow to advance with constant speed in the region $2 < \hat{x}_n < 7$. However, once the flow has become mixed and stratified, the reduced gravity throughout the current gradually decreases and
the flow adjusts to the self-similar regime in which the speed also gradually wanes (section 4). The data shown in panels b and c is typical of all our experiments.

3.2. Mixing at the head of the current

In order to build up understanding of how the mixing occurs, we have carried out a series of experiments in which we inject and then track a small volume of dye in both (i) the current and (ii) the ambient fluid. Figure 5 illustrates a gravity current of originally clear fluid advancing into a yellow ambient fluid (experiment Z, Table 1). In this experiment, a pulse of blue dye was injected into the current, at the position $\hat{x} = 2.4$, when the front of the current was at position $\hat{x}_n = 2.6$. Later a pulse of red dye was injected at the position $\hat{x} = 2.3$ when the front was at position $\hat{x}_n = 3.7$. Panels a-j, taken at equal dimensionless time intervals, illustrate how the blue and the red dye pulses migrate with time. In Figure 5b, we illustrate the density structure in an equivalent current, at 5 times, as obtained from a second identical experiment, Q. This second series of figures has been included in order to help relate the position of the dye relative to the current. As the flow continues along the flume, the blue dyed fluid catches up with the nose of the current. The front region of the current becomes blue and feeds a rising stream of dyed fluid which passes up over the top of the continuing gravity current. This forms a streak of blue fluid which propagates backwards relative to the nose of the continuing current (panels b-d). As the current advances the intensity of the blue dye decreases. Also, the red dye, which is initially injected in fluid further upstream in the current, progressively catches up with the front of the current.

In Figure 6a, we have plotted the dimensionless trajectories of the leading edge of a series of dye pulses injected into the currents which formed during different experiments.
Figure 6. Characteristic diagram in which (a) the trajectory of the leading edge of a series of parcels of dye injected within several of the experimental currents are followed in the $\hat{x} - \hat{t}$ plane. In this panel, the solid and dotted red lines correspond to the position of the leading edge of the gravity current and the point at which the contour on which the concentration is 0.95 of the original concentration meets the horizontal line $0.3h_{\text{cm}}$. In the insert, for each set of data, the position of the leading edge of the dye has been mapped so that the first point coincides with the origin. The insert shows that all the data collapses onto one curve, suggesting the fluid speed within the head is constant with position and time. Note that, based on our dye measurements, the fluid speed within the head is constant with position and time until $\hat{x} \sim 7$.

(b) The trajectories followed by a series of parcels of dye which are injected into the ambient fluid ahead of the current. The dye begins to move backwards as the front of the current arrives, and it continues to move backwards until the rear of the head passes by. The dye then slows down substantially, as the stratified tail of the current passes by. The dotted, dot-dashed and dashed red lines illustrate the points at which the contours where the concentration has value 95%, 70% and 50% of the original concentration in the fluid behind the lock gate, meet the line $y = 0.3h_{\text{cm}}$ (cf figure 4a). These lines gradually diverge as the tail spreads and the current becomes stratified. In panel a, data are shown from experiments R-V with the experimental data denoted as: R circles, S squares, T triangles, U diamonds and V stars. In panel b, data are shown for experiments W-Z, with data denoted as: W circles, X squares, Y triangles, and Z diamonds.
Figure 7. Illustration of the motion of three parcels of dye initially injected upstream of the gravity current near the base of the experimental tank (Experiment W, Table 1). The parcels of dye were injected at the positions $5 < x < 6$ at $\tau = 9.3$ (blue), $7 < x < 8$ at $\tau = 13.8$ (yellow), and $9 < x < 10$ at $\tau = 18.2$ (red). The panels show the location of the dye at a series of times as the current advances along the tank. The fluid in the gravity current initially has no dye.

(R-V). In the insert in this figure, we have mapped each set of data so that the initial position of the leading edge of the dye coincides with the origin, $(0,0)$. It is seen that, to reasonable approximation, the dye streaks from the different experiments advance with a uniform speed. This suggests that in these experiments the dye, and hence some of the fluid within the current travels at a speed up to $1.35 \pm 0.05$ times the speed of the front of the current. This is very similar to the speed of the rear of the gravity current head which we presented in figure 4a. Given the range of volumes and reduced gravities in the experiments which we have carried out, we suggest that this value is representative for high Reynolds number gravity currents in a finite depth ambient fluid, as explored herein.

On reaching the front of the current, the dyed fluid appears to rise up over the top of the current, mixing with some of the fluid originally ahead of the current, which is also displaced over the current. Once the current has passed by, this feeds the tail of the current. The precise process controlling the mixing may involve the mixing of ambient fluid initially overidden by the flow, and the incorporation of ambient fluid in the lobe and cleft structure of the head (cf. Simpson 1997, Buckee and Kneller, 2000). There are also eddies which appear to form on the upper surface of the head of the current, in
Figure 8. Cartoon illustrating the flow pattern during the initial mixing and dilution of the flow, as the current advances with a constant front speed. Fluid ahead of the current mixes with fluid reaching the front, then rises up over the advancing flow, and feeds the growing stratified tail of the current.

The flow pattern is reminiscent of Kelvin-Helmholtz billows, and these lead to the intermingling of the fluid displaced over the head of the flow with fluid from the head. This effective detrainment of original fluid from the head, and its circulation over the head to feed the tail of the flow rationalizes how there is a decrease in the volume of fluid which has the original concentration (figure 2, 3). The dye dispersal experiments for $\times_n > 7$, suggest that as the current becomes stratified, progressively more of the recirculating fluid can mix back into the rear of the head rather than supplying the tail. This leads to the formation of a density stratified current.

We now turn to the motion of the ambient fluid as the gravity current passes by, since this provides a complementary perspective on the mixing in the head region of the flow. In figure 7 we illustrate the evolution of three regions of dyed ambient fluid originally located ahead of the current (Experiment W, Table 1). As the undyed gravity current reaches each of the patches of dyed ambient fluid, it is seen that the ambient fluid rises over the current and mixes with some of the fluid at the front of the current. Panels a-c show the mixing of the blue dye, originally located in the region $5 < \dot{x} < 6$. Owing to the stratification in the wake, there is a weak shear flow which develops, and causes the blue dyed region to shear out in the wake, consistent with the velocity profile measured by Kneller et al. (1999) (section 4). Very little blue fluid appears to enter the head region.

Panels d and e show the evolution of a patch of yellow dye, initially located in the region $7 < \dot{x} < 8$. After rising over the top of the current, some of this yellow dyed fluid is mixed back into the head, which appears to include an anticlockwise vortex, and the remainder of the yellow fluid is dispersed into the wake. Panels e-g illustrate the mixing associated with a red patch of dye, initially located in the region $9 < \dot{x} < 10$. This mixes in a similar manner to the yellow dye, leading to further dilution of the head and growth of the wake immediately behind the head.

For comparison with the motion of the fluid originally in the current (figure 6a), in figure 6b, we show the trajectory of a series of parcels of dye injected into the ambient fluid initially ahead of the current. The leading edge of this dye appears to move backwards as the head passes. In the insert in figure 6b, for each data set, we have rescaled the time and position, so that the dye meets the front of the gravity current head at a rescaled
Figure 9. Variation of (a) the volume and (b) the height of the current head as a function of $\hat{x}_n$ in the region $0 < \hat{x}_n < 8$ containing the initial mixing zone, in which the fluid at the front of the current has the buoyancy of the fluid behind the lock gate. As the flow advances, there is a near linear increase in volume while the depth of the flow approaches a near constant value. Data is shown for experiments B-G and O-P, with data displayed with the following symbols: B crosses, C solid squares, D diamonds, E triangles, F stars, G plus, O circles, P hollow squares.

time of 0 and position 0. We then compare the speed of each dye pulse as it moves backwards towards the origin while the current passes by. The data are somewhat noisy but suggest that for $2 < \hat{x}_n < 7$, the dye located above the current, at position $\hat{x} < \hat{x}_n$, moves upstream with a speed which has value of about $0.66 \pm 0.05$ times the speed of the front of the current. In the main figure, for comparison, we also show the position of the front of the current (solid red line) and the position where the contours at which the concentration in the current has value 0.95, 0.7 and 0.5 of the original concentration meet the horizontal line $y = 0.3h_{cm}$. Figure 8 summarises the flow pattern during this initial mixing regime.

3.3. Entrainment coefficient during the mixing of the original lock fluid

We have measured the instantaneous volume of the current and the depth at a distance $H/2$ behind the front as a function of the distance travelled by the nose of the current, and this is shown in figures 9(a,b). The figure illustrates that there is some fluctuation in the volume and depth measurement associated, for example, with the time-dependent billow structures on the upper surface of the flow (figure 2). However, an ensemble average over all our experiments leads to the approximate relation that

$$\hat{V} = 1 + (0.31 \pm 0.02)\hat{x}_n$$

where $\hat{V} = \int_{\hat{x}_n}^{\hat{x}} \hat{h}(\hat{x})d\hat{x}$ while the depth of the head of the current tends to a value of about $\hat{h}_n = \hat{h}(x_n) \approx 0.38 \pm 0.04$ after an initial adjustment. We can define the fraction of the ambient fluid directly ahead of the current and which is entrained into the flow, $E$, by the relation

$$\frac{d\hat{V}}{dt} = E\hat{h}(x_n)\frac{d\hat{x}_n}{dt}.$$  

Using the values shown in figure 9, eqn (5) suggests that during the initial adjustment phase the entrainment coefficient lies in the range $0.7 < E < 0.8$.

During this initial dilution of the turbulent gravity current the fluid at the flow front
has density comparable to the initial value of the current. However, beyond this region
the mixing leads to a fully density stratified flow and a reduction in the buoyancy of all
the fluid. The different balance of the flow may then lead to a change in the entrainment
coefficient $E$ as defined by equation (5). In the following section we aim to determine the
entrainment coefficient further downstream as the flow becomes self-similar. Differences
in the entrainment rate during this initial adjustment and the subsequent self-similar
flow may lead to an effective virtual origin in time of the self-similar flow, as we account
for this in the analysis below.

4. The long-time self-similar regime

4.1. Experimental measurements of the head of the flow

We now present a series of measurements of the evolution of the speed of the head, the
reduced gravity of the head and the depth of the flow, once the current has advanced
beyond the initial mixing region, and become fully stratified. This provides the basis for
the development of a new model of gravity current dynamics including a description of
the entrainment at the head of the flow.

Numerous papers have proposed that during this second regime, the position of the
flow front should follow the scaling relation, obtained from dimensional arguments,

$$x_n(t) \sim B^{1/3}(t + t_o)^{2/3}$$

where we have included a time-offset $t_o$ to accommodate any difference in the rate of
dilution of the flow during the initial mixing phase described above. To test the scaling
in equation (6) we have calculated the ratio

$$X(t) = \frac{x_n(t)}{B^{1/3}(t + t_o)^{2/3}}$$

as shown in figure 10a. After an initial transient, $X \rightarrow 1.6 \pm 0.05$. In making the plot, we
have estimated a value for $t_o$ for each experiment to optimise the fit of the model, and,
in all cases, this has a value in the range $1 < t_o < 2s$, which is considerably shorter than
the 10-30s typical of the experiments. Since the value $t_o > 0$, we infer that in the initial
adjustment phase, the mixing is more rapid. The scaling (eqn 6) is in good accord with
earlier measurements of gravity currents (cf. Huppert and Simpson, 1982; Marino et al.,
2005).

We have measured the depth and concentration of the current at a distance $H/2$
behind the front of the current, as a representative value for the head of the flow (figures
10b, c). The depth data exhibits some fluctuation in value with time and also from
experiment to experiment (figure 10c). If we average over all the experiments, the mean
height appears to be approximately constant, with value $h/H = 0.38 \pm 0.04$, following
the initial adjustment of the flow to the self-similar regime (figure 11).

If the depth of the head of the current is approximately constant with time, then the
conservation of buoyancy suggests that the reduced gravity should decrease in proportion
to the lateral extent of the flow. We therefore expect the reduced gravity at the head of
the flow to decrease according to a relation of the form

$$\bar{g}'_n = G(t)B^{2/3}H^{-1}(t + t_o)^{-2/3}$$

where the dimensionless quantity $G(t)$ should tend to a constant following the initial
adjustment. Since the current is vertically stratified we work with the depth averaged
buoyancy, and define $\bar{g}'_n = g'_n H_n$, where we evaluate the vertically averaged salt concentra-
tion at the point $H/2$ behind the leading edge of the current. We have tested this scaling
Figure 10. Data from experiments H-N (Table 1) illustrating (a) the variation of \( X(t) = x_n(t)/B^{1/3}(t + t_o)^{2/3} \), the position of the nose of the current as a function of dimensionless time; (b) the variation with dimensionless time of \( G(t) = \Gamma_n(t + t_o)^{2/3}H/B^{2/3} \), where \( \Gamma_n \) is taken to have the value of the vertically averaged reduced gravity at a distance \( H/2 \) behind the front of the flow; (c) the variation with dimensionless time of the depth of the current at a distance \( H/2 \) behind the front of the flow. We have estimated the best fit value for the virtual release time, \( t_o \), and this has values in the range \( 1 - 2 \) s for all data shown. (d) Variation of the Reynolds number measured at a distance \( H/2 \) behind the front of the flow, as a function of the dimensionless position of the front of the current, \( x_n/L \), for each of the experiments shown in panels a-c. In each panel, the data from each experiment H-N are denoted by the following symbols: H plus, I1 solid squares, I2 hollow squares, J circles, K triangles, L diamonds, M crosses, N stars.

by measuring the value of \( G(t) \) (eqn 8) as a function of time for the different experiments H-N in Table 1 (figure 10b). It is seen that although there is some fluctuation, possibly associated with the turbulent fluctuations on the top surface of the flow near the head, \( G(t) \to 4.0 \pm 0.4 \) at long times (figure 10b, 11).

For each of the experiments shown in figure 10(a-c), the Reynolds number at the head of the flow, given by \( Re = \frac{h_n}{\nu} \frac{dx_n}{dt} \), where \( \nu \) is the kinematic viscosity, remained in excess of 4000 (figure 10d). In other experiments, for which the initial volume of fluid was smaller,
we found that once the Reynolds number at the head falls below a value of about 2500, the buoyancy of the head begins to decrease to smaller values than given by the scaling law (eqn 8), and the effects of the no-slip condition and viscous resistance from the base of the tank begin to influence the front of the flow (cf. Huppert and Simpson 1980). In this study, we focus on flows with higher Reynolds number, which appear to follow the self-similar scaling law (8).

In figure 11, we also show the average value of $Fr$, averaged over all the experiments shown in figure 10, as a function of dimensionless position, where $Fr$ is defined by the relation

$$\frac{dx_n}{dt} = Fr(f'_n h_n)^{1/2}$$

(9)

It is seen that $Fr \rightarrow 0.9 \pm 0.5$ once the current has passed through the initial adjustment region. This value is comparable to the values measured by Marino et al. (2005).

4.2. Structure of the current

The data presented above illustrate that mixing is central to the evolution of the gravity current; in order to understand the process of the mixing in some detail we have injected dye into the ambient ahead of the current at position $\hat{x} = 17$. We then follow the evolution of the dye as shown in the series of photographs in figure 12. It is seen that the dyed fluid rises up over the upper surface of the current as the current continues forward, and some of the dyed fluid mixes with current fluid, forming a region of intermediate density which extends forwards into the head of the current. These observations suggest that the displaced ambient fluid mixes with the gravity current fluid in the head region of the flow, and that as the mixture of current and ambient fluid rises up over the head, it supplies both the tail and the head of the flow, leading to a vertically and laterally stratified flow.
Figure 12. Illustration of the mixing of a parcel of dye injected ahead of the current at position $\hat{x} = 17$. Panels correspond to pictures taken at equal time intervals. The intense region of blue dye is carried over the head, and some of the blue dye is then stripped from it to form a streak of blue dye which extends forwards from the region of intense dye to the head of the current.

Figure 13. (a) Variation of the concentration as a function of the depth in the flow, as measured at a series of times and at a series of points $x/x_n = 0.2, 0.4, 0.6, 0.8$ as the current advances along the flume. (b) Ensemble average of the velocity profile from Kneller et al. (1999) and the concentration profile across the depth of the flow (panel a), with the data normalised to have a mean of unity over the depth of the flow. In panel b the vertical axes has been normalised so that the depth of the current is one. In panel a, data from experiment I1 is shown at positions $x/x_n$ given by: 0.8 solid, 0.6 dashed, 0.4 dotted, 0.2 dash-dotted, and for the times when the nose has position $\hat{x}_n$ given by: 19 green, 21.5 red, 24 black.
To explore this further, we have measured the vertical profile of the concentration in the current at a series of points along the current, and at different times, when the current has advanced different distances along the flume. In figure 13a, we show a series of vertical density profiles taken at points \( x/x_n = 0.2, 0.4, 0.6 \) and 0.8, for currents with \( x_n/L = 19.0, 21.5 \) and 24.0, in which we have normalised each profile relative to the maximum concentration on that profile. This illustrates that there is a significant vertical gradient of concentration, with a relatively dense lower part of the flow, overtopped by a mixed region. These data are consistent with that presented by Altinakar et al. (1996) for a gravity current produced from a maintained source. The structure of this stratification is similar along the length of the current, and also as the current migrates along the flume. In panel (b), we illustrate the ensemble averaged vertical buoyancy profile derived from (a), as well as the average velocity profile as reported by Kneller et al (1999). In this panel, we have normalised both the buoyancy and the speed so that they both have a mean of unity averaged over the depth of the flow.

We have also measured the variation of the vertical integral of the reduced gravity, \( \bar{g}'h = \int_0^h \bar{g}'(x,t)dy \) per unit length of the current, and the vertical extent of the current, \( h \), as a function of the position in the current, \( \eta = x/x_n \). The vertical integral of the reduced gravity has then been normalised with respect to the expression given in eqn (8), leading to the normalised quantity \( \bar{g}'(x)h/\bar{g}'_n h_n = \bar{s}/\bar{s}_n \) and this is shown as a function of \( x/x_n \) in figure 14a. In figure 14b, we show the variation of the depth of the current, normalised by the total depth of fluid in the flume, \( H \), as a function of \( x/x_n \). For a given current, the variation of \( \bar{s}/\bar{s}_n \) and \( \bar{h} \) with \( x/x_n \) is similar as the current advances from \( x_n = 12L \) to \( x_n = 21L \), although there is some scatter owing to the turbulent nature of the flow (cf. figures 2, 3). We have also calculated the time average of \( \bar{s}/\bar{s}_n \) and \( \bar{h} \) as a function of \( x/x_n \) for the 8 different currents, H-N, and the results are shown in figure 14 (c,d). It is seen that for each of these quantities, the variation with position in the current, \( x/x_n \), is similar from experiment to experiment, although there is some scatter, perhaps associated with the randomness of the turbulent fluctuations in the flow. We also note that as the current spreads along the flume to distances of order 20-25 lock lengths, then in the region of the lock gate, the current becomes very dilute and difficult to resolve accurately. In figure 14, we therefore only present the data in the region \( 0.15 < x/x_n < 1.0 \).

The data shown in figure 14 suggest that in the far-field, as the influence of the initial conditions becomes less important and the current becomes fully stratified, then the depth and vertical integral of the buoyancy adjust to a particular profile along the length of the flow. A circulation develops, with the denser fluid in the current being supplied to the front of the current from the lower part of the flow where the speed is a maximum (cf. Kneller et al. (1999), Altinakar et al. (1996), Thomas et al. (2003); figure 13). This fluid along with ambient fluid ahead of the current, rises over the top of the head, mixes and feeds the rear of the head and the tail of the flow with fluid of intermediate density (figure 1c; figure 15). Since the reduced gravity of the fluid in the lower part of the flow exceeds that higher in the flow (figure 13), we expect the vertical integral of the flux of reduced gravity to exceed the product of the vertically averaged velocity and the vertical integral of the reduced gravity at any point in the flow. As a result, surfaces of constant buoyancy travel faster than the mean flow speed and this may lead to the salinity being a maximum at the front of the current. Furthermore, the scalings for the evolution of the speed and buoyancy at the head of the current, combined with the details of the stratification in the flow, suggest that the flow is self-similar, with the mixing being a key part of the evolution. In the next section, we present a depth averaged model of the
Figure 14. Variation of (a) the dimensionless vertical integral of salt concentration, $\tilde{s}/\tilde{s}_n$, which is equivalent to $\tilde{\Phi}/\tilde{\Phi}_n \tilde{h}_n$, and (b) the depth, $\tilde{h}$, of the current, both as a function of the position within the current, $x/x_n$, for experiment I1. The different coloured curves shown in the plot correspond to those for which the head of the current had dimensionless position $x_n$ given by: 12 light blue, 13 dark blue, 14 light red, 15 green, 16 purple, 17 turquoise, 18 orange, 19 blue-grey, 20 pink, 21 dark red, 22 grey. (c, d) Time average structure of $\tilde{s}/\tilde{s}_n$ and $\tilde{h}$ as a function of the position, $\eta = x/x_n$, in the current, obtained by time-averaging over 20 profiles from the time when $x_n = 12$ to that when $x_n = 24$. Curves are shown corresponding to data collected from experiments H-N, as indicated by the colours: H orange, I1 solid black, I2 dotted black, J red, K green, L dark blue, M purple, N light blue.

flow based on these ideas, and the assumption that the entrainment of the ambient fluid occurs in the head region of the flow, as the fluid is displaced by the oncoming current, although there is subsequent mixing of this fluid into the oncoming current fluid as the mixture circulates back over the head of the flow.

4.3. The depth averaged model

In the data described earlier (figure 10), there are fluctuations associated with the turbulent motion, with typical eddy-turnover time $h/\bar{u}$, where $h$ and $\bar{u}$ are the depth and velocity scales of the flow. We are interested in the slow evolution of the flow relative to the local eddy turnover time, so we describe the motion in terms of the velocity, depth and buoyancy averaged over a time which is long compared to the eddy turnover time, in an analogous fashion to models of a turbulent buoyant plume (cf. Morton et al. (1956)). We compare the model predictions with the long-time evolution of the flow once the current extends over length scales much larger than $h$; at this stage the motion is dominantly parallel to the lower boundary, except in the vicinity of the front of the flow.
Applying the Boussinesq approximation, the local time-averaged equations for the conservation of mass, momentum and buoyancy, have the form

\[ \nabla \cdot \mathbf{u} = 0 \] (10a)

\[ \rho \frac{\partial \mathbf{u}}{\partial t} + \rho \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \rho g \] (10b)

\[ \frac{\partial g'}{\partial t} + \mathbf{u} \cdot \nabla g' = 0 \] (10c)

If we integrate the continuity equation, eqn (10a), across the depth of the flow, \( h \), and use the fact that on the upper surface of the current

\[ \frac{\partial h}{\partial t} + u(h) \frac{\partial h}{\partial x} = v(h) \] (11)

then we obtain

\[ \frac{\partial h}{\partial t} + \frac{\partial (h \hat{u})}{\partial x} = 0 \] (12)

We now integrate the momentum equation across the depth of the flow, \( h \). We use the fact that for a long thin current, the vertical pressure gradient is hydrostatic,

\[ p(x, y, t) = p_o(x, t) + \int_{y}^{H} \rho_o g dy' + \int_{y}^{h} \rho_o g' dy' \]

where \( p_o(x, t) \) is the ambient pressure along a horizontal surface of height \( H > h \) above the lower boundary, \( \rho_o \) is the ambient density, and \( g' = g(\rho - \rho_o)/\rho_o \). This leads to the result

\[ \int_{0}^{h} \rho \frac{\partial u}{\partial t} dy + \int_{0}^{h} \rho \left( \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) dy = -\int_{0}^{h} \frac{\partial}{\partial x} \left[ \int_{y}^{h} \rho_o g' dy' \right] dy - h \frac{\partial p_o}{\partial x} \] (13)
and combining this with the continuity equation (10a) and the boundary condition (11), we can express this equation in the form Gill (1981)

$$\frac{\partial (hu)}{\partial t} + \beta \frac{\partial (hu^2)}{\partial x} = -\gamma \frac{\partial (h^2 g')}{\partial x} - \frac{h}{\rho_0} \frac{\partial p_0}{\partial x}$$  \hspace{1cm} (14)

Finally, we can integrate the equation for conservation of buoyancy across the depth of the flow, and combining this with the continuity equation (10) and the boundary condition (12) we find

$$\frac{\partial (hg')}{\partial t} + \alpha \frac{\partial (hg' \bar{u})}{\partial x} = 0$$  \hspace{1cm} (15)

where

$$h \bar{u} = \int_0^h u dy \quad ; \quad \beta h \bar{u}^2 = \int_0^h u^2 dy \quad ; \quad hg' = \int_0^h g' dy$$

$$\alpha hg' \bar{u} = \int_0^h u g' dy \quad \text{and} \quad \gamma h^2 g'(x, t) = \int_0^h \int_y^h g'(x, y, t) dy' dy$$  \hspace{1cm} (16)

The coefficients $\alpha$, $\beta$ and $\gamma$ (Eqn 16) arise from the vertical distribution of $u$ and $g'$ in the flow, which is stratified in density and velocity (figure 13) and relate to the advection speed of reduced gravity and momentum relative to the vertically averaged flow speed. In the case that $\alpha > 1$ the advection speed of the depth averaged reduced gravity is greater than the depth averaged fluid speed, and this would result in the total mass of salt per unit length along the current being greatest at the front of the flow. This is in accord with our observations (figure 14) and we return to this observation below.

In this model, we assume the incorporation of the ambient fluid occurs in the head region of the flow; the strong circulation in the head of the flow causes a mixture of ambient and current fluid to rise up and flow back relative to the advancing front. As it rises up, the current fluid and ambient fluid mix, thereby producing a region of intense mixing on the top surface of the current in the neighbourhood of the front of the flow, over a region of lateral extent comparable to the depth of the flow (figure 12, 15). This mixed fluid then becomes incorporated into the tail and in part the head of the flow. The vertically stratified structure of the wake and the observations of the motion of streaks of dye suggest there is little mixing of ambient fluid directly into the wake further back from the head, above the main part of the current. We seek solutions to the model eqns (12,14,15) once the current has adjusted towards the apparently self-similar form, at which point the mixing region at the front of the flow is a relatively small part of the flow; therefore, as an approximation, we consider the mixing to occur at the front of the flow. We note that in our model we assume the shape factors for the vertical structure of the current are independent of position in the current. This simplification may not capture the full details of the structure of the flow in and near the head region of the flow where the mixing occurs.

In the model, we have neglected basal friction, since the Reynolds number at the head of the flow remains greater than 4000 (figure 10d), and in this case, we find that to good approximation, the experimental properties at the head of the flow follow the self-similar scalings (figure 10, 11a-c). However, friction will eventually become important (Huppert and Simpson, 1982; Hogg and Woods, 2001).

Equations (12, 14, 15) are to be solved with appropriate boundary conditions at the head of the flow, and subject to the constraint that a finite mass of buoyancy, $B$, was
Gravity Currents: Entrainment, Stratification and Self-Similarity

released from the origin, \( x = 0 \). The volume of the current is given by

\[
V = \int_0^{x_n} h(x, t) dx.
\] (17)

Using eqn (12), we also observe that

\[
\int_0^{x_n} \frac{\partial h}{\partial t} dx = -\int_0^{x_n} \frac{\partial \bar{u} h}{\partial x} dx = -\bar{u}(x_n) h(x_n).
\] (18)

Hence the evolution of the current volume follows a law of the form

\[
\frac{dV}{dt} = h(x_n) \left( \frac{dx_n}{dt} - \bar{u}(x_n) \right).
\] (19)

As in equation (5), we define the entrainment coefficient as the fraction of the ambient fluid displaced by the flow which is mixed into the flow. This is given by

\[
\frac{dV}{dt} = E h(x_n) \frac{dx_n}{dt} \quad \text{and so} \quad \bar{u}(x_n) = (1 - E) \frac{dx_n}{dt}.
\] (20)

We now assume \( E \) is constant in the self-similar flow regime, and our task is to determine \( E \) from the experimental data. It is worth remarking that eqn (19) requires that the depth averaged speed of the flow at the front is smaller than the rate of advance of the current. This is possible since the vertical shear in the horizontal velocity profile leads to some of the current fluid travelling faster than the vertically averaged speed; it is this fluid which recirculates over the head of the flow and mixes with the ambient fluid displaced from ahead of the current.

Conservation of buoyancy requires that

\[
\int_0^{x_n} h(x, t) g'(x, t) dx = B.
\] (21)

By comparing the terms in eqn (14), we expect that for a self-similar flow, the speed at the nose of the flow is given in terms of the Froude number \( Fr \) where

\[
\frac{dx_n}{dt} = Fr(\bar{u}_n h)^{1/2}.
\] (22)

This relation is also consistent with the direct measurement from the experiments (figure 11) which suggests that the value of \( Fr \), measured at the point a distance \( H/2 \) behind the front, tends to a constant with value \( Fr \rightarrow 0.9 \pm 0.05 \) downstream of the initial adjustment region (section 3).

4.4. Self-similar solutions

We now seek general self-similar solutions for this model system. In this context, we note that if the fluid has total depth \( H \) and the current has total buoyancy \( B \), then the parameter

\[
P = \frac{B t^2}{H^3}
\] (23)

is dimensionless, and so in principle the flow may depend on this parameter. However, guided by the experimental observations of the properties at the front of the current (figures 10, 11), we seek solutions of the form

\[
h(x, t) = H P^{\alpha_H} H(\eta) \quad ; \quad g'(x, t) = \frac{B^{2/3}}{t^{2/3} H} P^{\beta_H} G(\eta) \quad ; \quad \bar{u}(x, t) = B^{1/3} t^{-1/3} P^\alpha U(\eta)
\] (24)
where $\eta = x/x_n(t)$ and $x_n(t) = \lambda B^{1/3}t^{2/3}/P^d$. Although we have included the possible dependance on $P$ to make the derivation general, given the experimental observations (figures 10, 11), we expect that the appropriate self-similar solutions to not depend on $P$ (see below).

If we substitute the ansatz (eqn. 24) into the depth averaged equations, and apply the boundary conditions, we can find the exponents $a, b, c$ and $d$ and the shape functions $\mathcal{H}, \mathcal{U}$ and $\mathcal{G}$. The conservation of buoyancy in the current (eqn 21) requires that the exponents satisfy

$$a + b + d = 0$$

while the Froude number condition at the head of the flow requires that

$$2c = a + b.$$  \hspace{1cm} (26)

Finally, we require that the speed of the flow at the nose, $\bar{u}(x_n, t)$ is proportional to the rate of advance of the nose, $dx_n/dt$ and so $c = d$. Combining these three relations requires that

$$c = d = 0 \text{ and } a = -b.$$  \hspace{1cm} (27)

In the special case of a finite depth of fluid, for a self-similar solution, we expect the depth of the head of the flow to be a constant fraction of the depth of the fluid layer, so that near the head, the flow in the ambient fluid which is displaced by the current, but not entrained, is also self-similar; this additional condition suggests that $a = b = 0$. This is consistent with our measurements (figure 10b). These arguments suggest that the solution (eqn 24) is independent of $P$, as suggested by the data (figure 11).

We deduce that

$$x_n(t) = \lambda B^{1/3}t^{2/3}$$

where $\lambda$ is a constant. Also, by substitution of the (eqn 24) into the conservation equations (12, 15), we find the ordinary differential equations governing the variation of reduced gravity, depth and speed

$$\left(-\frac{2\lambda \eta}{3} + \mathcal{U}\right) \frac{d\mathcal{H}}{d\eta} = -\mathcal{H} \frac{d\mathcal{U}}{d\eta}$$  \hspace{1cm} (29)

$$-\frac{2\lambda \eta}{3} \frac{d}{d\eta} (\mathcal{G}\mathcal{H}) + \alpha \frac{d\mathcal{G}\mathcal{U}}{d\eta} = 0.$$  \hspace{1cm} (30)

For such a self-similar solution, we then expect the pressure $p(x, t)$ to follow a scaling of the form $p(x, t) = \rho_0 B^{2/3}t^{-2/3}F(\eta)$, where $\rho_0$ is a reference density, so that on substitution into eqn (14) we obtain

$$-\frac{\lambda}{3} \mathcal{U}\mathcal{H} + \frac{2\lambda \eta}{3} \frac{d\mathcal{H}\mathcal{U}}{d\eta} + \beta \frac{d\mathcal{H}^2\mathcal{U}}{d\eta} = -\frac{d\mathcal{H}^2\mathcal{G}}{d\eta} + \mathcal{H} \frac{d\mathcal{F}}{d\eta}$$  \hspace{1cm} (31)

As a simple ansatz motivated by the profiles in figure 14, if we assume the velocity, reduced gravity and depth are given by power laws of $\eta$, then equation (30) requires

$$\mathcal{U} = \frac{4\lambda \eta}{9\alpha}$$  \hspace{1cm} (32)

where we have equated the exponent of $\eta$ on the left hand side with the first term on the right hand side of eqn (31) to infer that

$$\mathcal{H}\mathcal{G} = \mathcal{H}_1\mathcal{G}_1\eta^2.$$  \hspace{1cm} (33)
Eqn (29) then requires
\[ H = H_i \eta^\frac{2}{3\alpha} \]  
(34a)
and so
\[ G = G_i \eta^6(\frac{2}{3\alpha}) \] 
(34b)
where \( H_i \) and \( G_i \) are constants. We see from the solution eqn (34) that providing \( \alpha > 1 \),
then in this self-similar flow regime, the depth and the reduced gravity increase towards
the front of the flow, in accord with the experimental data (figure 14). Note that the
pressure term, which arises in equation (31), can also be evaluated from the model given
the solution for the speed, depth and reduced gravity.

Using the solution, equation (20) suggests that the fraction of the displaced fluid which
is entrained into the current is given by
\[ E = 1 - \frac{2}{3\alpha}. \] 
(35)
Also, the conservation of total buoyancy (eqn 21) requires that
\[ H_i G_i = \frac{3}{\lambda}. \] 
(36)
Substituting the solutions into the Froude number condition (eqn 22), and combining
with eqn (36) we then find that
\[ Fr = 2\left(\frac{\lambda}{3}\right)^{3/2}. \] 
(37)

According to this solution, the fraction of the displaced fluid mixed into the current
\( E \), and also the shape of the current, \( H(\eta) \), are controlled by the parameter \( \alpha \), while,
independently, the conservation of buoyancy and the Froude number impose constraints
on \( \lambda, G_i \) and \( H_i \). We now compare the model with our experimental results.

4.5. Mixing during self-similar regime

In order to predict the mixing rate, we need to estimate the value of \( \alpha \) (eqn 35). To
this end, we compare the variation of the depth of the flow as a function of position
in the current as predicted by the model with the experimental data (figure 14). We
have taken the time average of the current depth for the 8 different experiments shown
in figure 14d, and in figure 16b we compare these with the theoretical model (eqn 34a)
using the values \( \alpha = 1.8, 2.3 \) and 2.8.

In comparing the model with the experimental measurements of the depth profile,
we note there is some significant scatter in the data, with local differences between the
model and the concentration data being as large as 50% near the transition from the
head to the tail. We suggest that some of these results from the turbulent nature of
the flow, which leads to variations from experiment to experiment, but there is some
systematic difference, especially in the depth averaged buoyancy just behind the head. It
may be that the vertical structure of the current does in fact vary along the current, and
especially in the region of the head, whereas for simplicity, we have assumed that this is
constant in our model, but assessment of this is beyond the scope of our measurements.
Nonetheless, the model seems to provide a reasonable leading order description of the
overall behaviour of the flow, if not the local buoyancy just behind the head, and we find
that for values of \( \alpha \) in the range 1.8 – 2.8, the absolute fractional difference between the
area of the theoretical model (eqn 34a) and the average of the 8 experimental profiles
Figure 16. Variation of (a) the vertical integral of the salt concentration, normalised by the vertical integral of the salt concentration at the nose, $\bar{s}/\bar{s}_n$, which is equivalent to $\bar{\gamma}_{\text{h}}/\bar{\gamma}_{\text{h},n}$, as a function of position in the current, $x/x_n$, for the 8 experiments H-N. For comparison the model solution (33) is also shown with the thick black curve, rescaled to have value 1 at $\eta = 1$ to be consistent with the dimensionless data; and (b) time average of the depth of the current as a function of the position within the current (cf. figure 14), again compared to the theoretical model prediction eqn (34a) for the dimensionless current depth using the values $\alpha = 1.8, 2.1$ and 2.8. Data collected from experiments H-N are indicated by the colours: H orange, I1 solid black, I2 dotted black, J red, K green, L dark blue, M purple, N light blue. Thick lines correspond to the idealised similarity solution. In panel c we present a colour image in which we compare the fraction of the total buoyancy of the current in the region of the current between the rear of the lock gate and each point in the current, as a function of the dimensionless position in the current (x-axis) and dimensionless time (y-axis). The colour corresponds to this fraction as indicated on the legend, and contours corresponding to fractional values 0.1, 0.2, ..., 0.9 are also shown on the figure. In figure 16d we show a colour image of the fraction of the total volume of the current in the region of the current between the rear of the lock gate and each position in the current, as a function of the dimensionless position (x-axis) and dimensionless time (y-axis). We also include contours of constant volume fraction 0.1, ..., 0.9 in the figure.

shown in figure 14d, $h_0(\eta)$ say, as defined by

$$
err_h = \frac{\int_0^1 |h_0(\eta) - \bar{H}_n\eta^{\alpha-2} \bar{\gamma}_h(\eta)| d\eta}{\int_0^1 \bar{H}_n\eta^{\alpha-2} d\eta}
$$

(38)

is less than 10%. This range of values of $\alpha$ corresponds to values of $E$ in the range 0.63 – 0.76.

As an independent check on the value of $E$, we can estimate $\alpha$ from the vertical profile
for the speed and reduced gravity of the flow (eqn 16). Using the data presented in Kneller et al. (1999) for the speed and the present experiments for the reduced gravity (figure 13), we can apply eqn (16) to calculate \( \alpha \). Accounting for the uncertainty in the measurement of concentration in the upper part of the flow, where the flow is quite dilute and where the velocity is negative, leads to an estimate for \( \alpha = 1.9 \pm 0.3 \).

The two different measurements for \( \alpha \) overlap in the range \( 1.8 < \alpha < 2.2 \), and for this range, eqn (35) suggests that \( E \), the fraction of the fluid displaced by the head which mixes into the current, has a value in the range \( 0.63 < E < 0.7 \). This is smaller than our estimate for the entrainment coefficient during the initial adjustment phase of the flow. The difference is consistent with there being a positive value of \( t_o \), the correction to time in the self-similar solutions (figure 10); the enhanced mixing during the initial slumping phase is equivalent to the current being released earlier.

4.6. Model parameters

The experimental measurements of the buoyancy and depth at a point \( H/2 \) behind the front of the flow suggest that \( \mathcal{H}_i = 0.38 \pm 0.04 \) while \( \mathcal{G}_i = 4.0 \pm 0.4 \) (fig 10b,c) so that \( \mathcal{G}_i \mathcal{H}_i \approx 1.52 \). However, from figure 10a, we estimate that \( \lambda = 1.6 \pm 0.05 \). The conservation of buoyancy, eqn (36) suggests that \( 3/\mathcal{H}_i \mathcal{G}_i = \lambda \). Taking the range of values for \( \mathcal{H}_i \) and \( \mathcal{G}_i \), we find that the data suggest \( 3/\mathcal{H}_i \mathcal{G}_i = 2.0 \pm 0.4 \). Although the lower bound of this range coincides with the value of \( \lambda \) obtained from eqn (6) and figure 10a, \( \lambda = 1.6 \), there is a suggestion that an additional process is affecting the experiments.

Also, using the value \( \lambda \approx 1.6 \pm 0.05 \) (figure 10a), and combining with eqn (37), we predict that the effective Froude number in this stratified flow is \( F_r \approx 0.79 \pm 0.03 \). The actual measurement of the Froude number at a distance \( H/2 \) behind the front, based on the actual depth integral of the reduced gravity and the speed of the flow, is \( 0.9 \pm 0.05 \) (figure 11). The model prediction is within about 12% of the measurements, but again there is a suggestion of some difference between the model and the data.

In order to investigate this further, in figure 16a, we compare the normalised experimental data (figure 14c) with the model prediction, eqn (33), for the variation of the vertical integral of the reduced gravity, normalised by the value at the nose, \( \mathcal{G}_i \mathcal{H}_i / \mathcal{G}_i \mathcal{H}_i \), as a function of \( \eta \). Note, the theoretical model is scaled by \( \mathcal{G}_i \mathcal{H}_i \), so that the scaled value is one at \( \eta = 1 \), consistent with the normalised experimental data. Although the general trend in the experimental data is similar to the model prediction, there appears to be a systematic difference between the data and the model in the tail of the flow, where the measured vertical integral of reduced gravity is larger than the model prediction. This difference suggests that some of the saline solution released from behind the lock gate becomes detached from the front of the gravity driven flow. Given that the speed at the rear of the flow near the lock gate is much smaller than that near the front of the flow, it is likely that the no-slip condition near the base of the tank leads to a finite, but small, part of the flow near the source becoming detached from the ongoing current. Provided that this loss of buoyancy occurs relatively slowly compared to the rate of advance of the flow, we expect that, following the initial adjustment of the flow, the current will evolve approximately according to the self-similar dynamics, but that it then gradually evolves from pure self-similar behaviour as progressively more buoyancy is lost at the rear of the flow. In the experiments, the self-similar regime of the flow seems to apply approximately in the region \( 12 < x_n < 22 \) (figure 10), where the properties of the head follow the scaling laws (6) and (8). In the initial slumping phase of the flow, a small part of the source fluid in the tail of the flow may become detached from the continuing head in this lower boundary layer. There may then be a slowly increasing mass of fluid which becomes detached from the rear of the current as it spreads, dilutes
and slows. We therefore interpret the measurements of $\lambda$ and $G_\lambda$ as relating to the average of the effective buoyancy in the current over the interval $12 < x_n < 22$. In order to estimate this active or effective buoyancy driving the current, we now carry out a very simple approximate analysis. We assume that, in the region $12 < x_n < 22$, the active current only sees a fraction $f$ of the total buoyancy released from behind the lock gate. Equations (6) and (8) would then imply that, based on this reduced buoyancy in the current, $\lambda = (1.6 \pm 0.05)/f^{1/3}$ while $G_\lambda = (4.0 \pm 0.4)/f^{2/3}$. Conservation of buoyancy (eqn 36) would then suggest that $f = 0.8$, in order that $\lambda G_\lambda H_\lambda = 3$ and so the best fit values are $\lambda = 1.7$ and $G_\lambda = 4.6$ to two significant figures. Using this larger value for $\lambda$ we predict, from eqn (37), that the Froude number of the flow is $0.87 \pm 0.04$, which is also much closer to the experimental observations. Given the agreement with the speed, the reduced gravity at the front of the flow, the conservation of total buoyancy and the Froude number at the front of the flow, we propose that these revised values correspond to those which would apply to a very high Reynolds number inertial current in which the no slip boundary effects are very small. It is worth noting that the integral of the absolute difference between the model prediction for the vertical integral of the salinity in the current and the average of the experimental data for the 8 experiments shown in figure 16a, as a fraction of the total salinity in the current,

$$e_{rrs} = \frac{\int_0^1 |\hat{s}(\eta) - \eta^2| \, d\eta}{\int_0^1 \eta^2 \, d\eta}$$

(39)

is also about 16% which is similar to the fraction of the buoyancy which has been estimated to be left in a boundary region in the tail of the flow $1 - f = 0.2$. Since all of the currents have a similar initial volume in our experiments, we expect that the value of $f$ is also similar from experiment to experiment. Unfortunately, we could not experimentally test the dependence of $f$ on much larger variations in initial volume, since with much smaller initial volume, the Reynolds number of the flow becomes too small for the front of the flow to remain in the inertial regime, while our experimental system is too small admit significantly larger source volumes.

In order to demonstrate this slow loss of buoyancy from the rear of the current, in figure 16c we present a colour image in which we compare the fraction of the total buoyancy of the current in the region of the current between the rear of the lock gate and each point in the current, as a function of the dimensionless position in the current (x-axis) and dimensionless time (y-axis). The colour corresponds to this fraction as indicated on the legend, and contours corresponding to fractional values 0.1, 0.2, ..., 0.9 are also shown on the figure. It is seen that, gradually, the dimensionless position of each contour representing a constant fraction of the buoyancy migrates backwards in the current. This redistribution of the buoyancy is consistent with a slow loss of buoyancy from the rear of the current. Our earlier estimate that the effective buoyancy driving the leading part of the flow $12 < x_n < 22$ is about a fraction 0.8 of the total buoyancy, is consistent with the contours in figure 16c.

For comparison, in figure 16d we show a colour image of the fraction of the total volume of the current in the region of the current between the rear of the lock gate and each position in the current, as a function of the dimensionless position (x-axis) and dimensionless time (y-axis). We also include contours of constant volume fraction 0.1, ..., 0.9 in the figure. The image shows that in the region $x_n > 10$, after the current has adjusted, then to good approximation, the volume contours are independent of the dimensionless position of the current. This suggests that even though there is a slow loss of buoyancy from the dense lower part of the flow, the current shape remains approximately
the same as the current advances. Together, these figures show that strictly the flow is not self-similar owing to the slow redistribution of buoyancy from the front to the rear of the flow. However, this redistribution of buoyancy is a slow process and so the self-similar depth-averaged model seems to provide a reasonable approximate description of the overall dynamics of the gravity current following the initial transition of the flow (section 3). The details of the entrainment and mixing at the front of the flow have been parameterised by the mixing coefficient $E$ which suggests a fraction $0.63 - 0.76$ of the fluid displaced by the current is mixed into the current. We also suggest that in our experiments, about 20% of the initial buoyancy of the flow becomes detached from the main advancing flow in a boundary region near the base of the tank in the tail of the flow. In future work, amongst other challenges, it would be of interest to explore the details of the circulation at the front of the flow in more detail and also to quantify the controls on the slow redistribution of buoyancy seen in figure 16c.

5. Discussion

We have presented a new suite of experiments in which we measure the mixing throughout a gravity current produced by the release of a finite mass of dense fluid from behind a lock gate. During the initial motion, the unmixed dense fluid within the head of the current advances at a speed of order $(1.35 \pm 0.05)u_n$, where $u_n$, the speed of the front of the current, has value $u_n = (0.9 \pm 0.05)(g'h)^{1/2}$. As a result, unmixed current fluid arrives at the front of the flow, rises up over the continuing flow and slows down, migrating backwards relative to the front. The recirculating fluid mixes with about $0.75 \pm 0.05$ of the ambient fluid, originally downstream of the current, which is also displaced upwards and backwards by the current. The mixture is then supplied to the tail behind the advancing flow. The trailing edge of the region of original unmixed fluid in the head, which coincides with the ‘bore’ observed by Rottman and Simpson (1983), catches the front of the flow when the front has travelled to a point about seven lock lengths downstream, $\hat{x}_n = 7$ (figure 2). As the current advances beyond this point, the circulation and mixing persist and there is a progressive decrease in the maximum density of the head (figure 3, 4). The current becomes laterally and vertically stratified, with the reduced gravity increasing towards the head.

The continuing flow gradually adjusts to a self-similar profile in which a fraction $0.63 - 0.7$ of the fluid displaced by the current mixes into the current. This mixing appears to occur largely in the head region of the flow and, with the circulation, leads to formation of a substantial vertical and lateral stratification in the current. As the flow advances, the depth of the head remains nearly constant, while the buoyancy of the front of the flow decreases inversely with the position of the nose downstream. This leads to a near linear increase in the volume of the current as the nose advances downstream. Our data is consistent with the classical self-similar result that the position of the nose, $x_n(t) = 1.7B^{1/3}t^{2/3}$, and the data suggests that the effective Froude number of the head of the flow is about $0.9 \pm 0.05$. However, in this self-similar regime, we find that the mixing of ambient fluid into the flow causes the vertically averaged reduced gravity at the head of the flow to decrease according to the relation $\tilde{g} = 4.6B^{2/3}H^{-1}t^{-2/3}$. We develop a new self-similar model, derived from the depth-averaged equations, by assuming that the mixing with the displaced ambient fluid occurs in the head of the flow. The predictions of this model are in reasonable accord with the measured profiles of the depth averaged reduced gravity and the depth of the flow and lead to the prediction that a fraction $0.69 \pm 0.06$ of the fluid displaced by the current is mixed into the flow. A key element of the model is that owing to the stratification, the depth-averaged advection speed of the
reduced gravity exceeds the depth averaged speed of the fluid, and so the reduced gravity is maximal at the front of the flow and gradually decreases upstream in the tail. Our data do show however, that there is a slow redistribution of buoyancy from the front and towards the tail of the flow, and so strictly the experimental flows are not self-similar.

The mixing process we have described has numerous implications for density driven flows in nature and the environment and we plan to explore these in forthcoming work. We are also presently exploring the implications of the mixing of ambient fluid into the current, as described herein, in the different context of a maintained source of buoyancy and also in an axisymmetric geometry (Samasiri & Woods 2015). In both cases the detailed dynamics controlling the value of the entrainment parameter $E$ are different, and we plan to report on these studies in the near future.

We are grateful for the helpful comments of the referees and for the support of BP in funding this work.
