ABSTRACT

We present new results on [CII]158\mu m emission from four galaxies in the reionization epoch. These galaxies were previously confirmed to be at redshifts between 6.6 and 7.15 from the presence of the Ly\alpha emission line in their spectra. The Ly\alpha emission line is redshifted by 100-200 km s^{-1} compared to the systemic redshift given by the [CII] line. These velocity offsets are smaller than what is observed in z ~ 3 Lyman break galaxies with similar UV luminosities and emission line properties. Smaller velocity shifts reduce the visibility of Ly\alpha and hence somewhat alleviate the need for a very neutral IGM at z ~ 7. These low-redshift Ly\alpha break galaxies with similar star formation rates. We argue that previous undetections of [CII] in z ~ 7 galaxies with similar or smaller star formation rates are due to selection effects: previous targets were mostly strong Ly\alpha emitters and therefore probably metal poor systems, while our galaxies are more representative of the general high redshift star forming population.

Subject headings: galaxies: evolution — galaxies: high-redshift — galaxies: formation

1 INTRODUCTION

We have just entered an exciting era when cosmic microwave background observations can be directly compared to observations of the first galaxies. Reionization is thought to begin at z ~ 10 – 15 and be completed by z ~ 6 (Robertson et al. 2015), but how exactly it proceeded in time is still the subject of debate. Understanding the nature of the sources responsible for such process is also an outstanding problem of modern cosmology: both faint galaxies (e.g. Finkelstein et al. 2015) and AGNs (Giallongo et al. 2015) can potentially contribute to reionization and the exact role of the two populations is still unclear.

Deep multi-band imaging surveys identified a large number of candidate galaxies at z > 6 and up to z ~ 10 primarily using the Lyman Break technique but their spectroscopic confirmation has been difficult. At present very few galaxies at z > 7 are confirmed (e.g. Finkelstein et al. 2015, Oesch et al. 2015, Zitrin et al. 2015). Indeed the extreme difficulty in securing the redshifts of z-dropouts is the first (and perhaps most solid) evidence that the reionization of the Universe was not yet complete at z ~ 7. This marked decrease of Ly\alpha emission at z ~ 7 compared to z ~ 6 is best explained by an increased opacity of the intergalactic medium (IGM) with neutral hydrogen fraction change between the two epochs of $\Delta x_{\text{HI}}$ ~ 0.5 (Pentericci et al. 2014, Schenker et al. 2014). The physical properties of these galaxies are also uncertain. Star formation rates (SFR) based on UV-luminosity give values of ~ 10–15 $M_\odot$ yr^{-1}. However dust is surely present even if in small amounts, at such early epochs (Watson et al. 2015) and can strongly suppress the UV-continuum. Accounting for this may easily raise the inferred SFR to several tens $M_\odot$ yr^{-1}.

ALMA can play a key role in settling the above issues and assess the nature of high redshift galaxies. The [CII]157.74\mu m line, the strongest FIR emission lines in star forming galaxies (accounting for 0.1-1% of their bolometric luminosity), is accessible by ALMA even at the highest redshifts probed to date. [CII] can provide SFR estimates that are not biased by dust extinction, although they might depend on the metallicity. In addition this line allows us to accurately measure the systemic redshift of the galaxies. The recent [CII] line detections of Lyman Break galaxies (LBGs) and Ly\alpha emitters (LAEs) at z ~5.5-6 (Capak et al. 2015, Willott et al. 2015) show that the line properties at such high redshifts are similar to those at lower redshift and that they follow a comparable SFR-L[CII] relation (de Looze et al. 2014). The observed galaxies represent the bright end of the UV luminosity function. On the fainter end, Knudsen et al. (2016) detected [CII] in the strongly lensed galaxy A383-5.1. At variance with the above picture, the few observations attempted on z ~ 7 galaxies with ALMA provided contradictory results (e.g. Ota et al. 2012, Schaerer et al. 2014, Maiolino et al. 2015, Watson et al. 2015): several non-detections of [CII] suggested that z ~ 7 galaxies have [CII] emission significantly below the expectations from lower redshift relations, although the small number of sources observed and the shallow limits reached for some of them give an uncertain scenario. We previously reported of [CII] observations on three z ~ 7 galaxies (Maiolino et al. 2015): for two of them we set quite stringent...
constraints on the non-detection of the [CII] line, whereas the third one showed a detection from a region that is not centered on the galaxy. None of the $z \sim 7$ galaxies are detected in the far-IR continuum, which suggests a low dust mass. The only exception is A1689-zD1 at $z \sim 7.5$ with a clear detection of thermal dust emission (Watson et al. 2015). The above results suggest a change in galaxies’ physical properties between $z \sim 6$ and $z \sim 7$.

In this work we present new observations of [CII] in four LBGs at $z \sim 7$. Throughout the paper, we adopt a cosmology with $\Omega_\Lambda = 0.7$, $\Omega_M = 0.3$ and $H_0 = 70$ km/s/Mpc. Magnitudes are in the AB system.

2. SAMPLE SELECTION AND OBSERVATIONS

We have recently completed CANDELSz7, an ESO spectroscopic large program using FORS2 at the VLT. Our goal is to systematically study the Ly\textalpha emission in galaxies from $z=5.5$ to $z=7.2$ selected in the CANDELS fields (Grogin et al. 2011, Koekemoer et al. 2011). With the addition of previous data we have assembled a sample of $>120$ LBGs at $z \sim 7$ with homogeneous selection and deep spectroscopic observations (Pentericci et al. in preparation). In about 20% we detect the Ly\textalpha line, with EW in some cases as low as 5 Å. From this sample we have selected the seven brightest galaxies with: (1) precise redshifts between 6.6 and 7.2 from Ly\textalpha emission; (2) SFR $> 15 - 30 M_\odot yr^{-1}$ based on UV emission, assuming the Kennicutt (1998) calibration with no dust correction. While these LBGs all have Ly\textalpha emission, the majority of them would not be selected by the usual LAE criteria because the lines only have modest EW.

During Cycle-3 we obtained observations for four of the seven galaxies approved in program 2015.1.01105.S. In Table 1 we show their optical properties. NTTDF6345 was part of one of our early studies (Pentericci et al. 2011), while the other galaxies were confirmed by CANDELSz7. COSMOS13679 has been independently confirmed by Stark et al. (2016). In Table 1 the coordinates reported are the HST H-band centroids in all cases except for NTTDF6345, which was detected with HAWK-I in Y-band (Castellano et al. 2010). For NTTDF6345 we had previously obtained lower S/N data in Cycle-2 (prog. 2013.1.01031.S).

Objects were observed with ALMA in band 6 which has baselines between 14.7 and 376.9 meters, and provides a minimal resolution of 0.9\arcsec. The center of the band was set at the redshift corresponding to the peak of the Ly\textalpha emission. Sensitivity was set to reach $\sim \log(L_{[\text{CII}]}) = 7.5$ (with $L_{[\text{CII}]}$ in $L_\odot$). Observations were performed in Frequency Division Mode. Out of the four spectral windows, SPW1 was centred on the expected frequency of the [CII] line in the Upper Side Band. This spectral band was set to a spectral resolution of 10 km \textperpend s$^{-1}$. SPW0 was located on the continuum next to SPW1 (on the higher frequency side), while SPW2 and SPW3 were located in the Lower Side Band to sample the continuum. The ALMA observations were carried out from April 2015 to March 2016. The number of antennas ranged from 36 to 46. The precipitable water vapour during the observations ranged between 0.82 and 3.0 mm. The phases were centred at the positions reported in Table 1. The data were reduced with the Common Astronomy Software Application (CASA) and the final images were produced using the CLEAN task. The continuum image of each target was extracted using all the line-free channels of the four spectral windows, while spectral cubes were generated from the SPW1 dataset.

![Figure 1](image-url). S. Spectra of the four galaxies in the region of the [CII] emission line. The velocities are shown with respect to that inferred from the Ly\textalpha which is marked with the dashed vertical lines.
3. RESULTS

3.1. [CII] line detections

In Table 2 we present our results: a [CII] emission line is detected for the three sources observed only in Cycle-3, with a S/N=4.5. For NTTDF6345 an emission line is observed separately in the Cycle-2 and Cycle-3 data-sets with a S/N of 4.1 and 5.6 respectively, and a S/N>6 is obtained in the combination. Although the S/N is modest, the spatial coincidence (or very close spatial association) between the [CII] and the near-IR counterparts, and the consistent small shift with respect to the redshift determined from the Ly$\alpha$ emission all argue for the reality of the detections. In addition in three out of four cases the detections are spatially resolved. In Figure 1 for each source we present the spectrum of the [CII] region with a rebinning of 40 km s$^{-1}$ for NTTDF6345 and 20 km s$^{-1}$ for the other sources: the vertical dotted line at v=0 km s$^{-1}$ indicates the redshift determined from the Ly$\alpha$ emission. The maps of the line emission are shown in Figure 2, extracted with a spectral width of 440 km s$^{-1}$ for NTTDF6345, 280 km s$^{-1}$ for COSMOS24108, 100 km s$^{-1}$ for UDS16291 and 120 km s$^{-1}$ for COSMOS13679. The black crosses indicates the centroid of the Y-band image for NTTDF6345 and of the HST H-band images for the other galaxies.

Thermal far-infrared continuum is not detected in any of the galaxies: the limits on the total IR-luminosity convert into limits on the dust obscured SFR that are reported in Table 2 (assuming a Kennicutt (1998) relation with a Salpeter initial mass function).

3.2. Offsets between [CII] and rest-frame UV position

In Table 2 we report the offset between the near-IR coordinates and the ALMA detections. In two cases the shifts are consistent with the ALMA astrometric uncertainty (0.1-0.15″), while for COSMOS24108 and COSMOS13679 they are larger. Dunlop et al. (2016) recently noted that the HST and ALMA astrometry of the HUDF field presented both a systematic shift of 0.25″ to the south and a random shift of up to 0.5″. Spatial offsets of up to 0.5″ are clearly evident in most of the LBGs observed by Capak et al. (2015) and for the $z \sim 6$ galaxy WMH5 observed by Willott et al. (2015) (0.4″), while in the other galaxy CLM1, the [CII] emission is co-spatial with the UV continuum.

To further investigate this issue we looked at bright serendipitous sources detected in the continuum band in our fields. We find at least one source per field and we measure a shift between 0.1″ and 0.6″ in random directions between the HST (or HAWK-I) counterpart and the ALMA detection. Given the depth of the CANDELS images ($H \sim 27$ at 5σ) it is unlikely that the ALMA detections are associated to other objects undetected in the H-band. Note that for NTTDF6345 where we only have HAWK-I images, the shift is negligible both for the serendipitous source and the LBG. We conclude that there are still substantial uncertainties in the relative ALMA-HST astrometry. In summary, for UDS16291 and NTTDF6345 the [CII] detections are centered at the position of the near-IR sources, and for COSMOS13679 the offset (0.4″) is within the range of those reported in the literature and measured for the serendipitous sources: for these three galaxies we conclude that the [CII] emission comes from the same region as the bulk of the SF observed in the near-IR images. For COSMOS24108 the offset is slightly larger than the range reported in the literature, and while the [CII] emission is almost certainly associated to the source, it could actually come from an external region of the galaxy, not coincident with the bulk of the star formation. A similar case was already observed in BDF3299 at $z=7.109$ (Maïolino et al. 2015): for this galaxy we concluded that the [CII] emission arises from an external accreting/satellite clump of neutral gas, in agreement with recent models of galaxy formation (Vallini et al. 2015). While the identification with another transition from a foreground galaxy, which by chance happens to be at 0.8″ from COSMOS24108, is unlikely, we cannot completely discard the possibility of a spurious detection given the low S/N.

4. DISCUSSION

4.1. [CII] - Ly$\alpha$ velocity shifts

The [CII] line traces the systemic redshift of the sources, unlike the Ly$\alpha$ line which is typically red-shifted by up to several hundreds km s$^{-1}$ (Erb et al. 2014, Trainor et al. 2016) consistent with the presence of outflowing gas, although the final observed Ly$\alpha$ profiles depend on many factors such as geometry, gas covering fraction, dust and IGM ionization state. For our galaxies the velocity shifts are not very large, of the order of 100-200 km s$^{-1}$, smaller than those reported at $z \sim 3$ for galaxies with similar UV luminosities. Specifically Erb et al. (2014) measure shifts of up to 1000 km s$^{-1}$ and average values of 400 km s$^{-1}$ for LBGs with $M_{UV} < -21$. The mean shift is also lower than those reported by Willott et al. (2015), 430 and 275 km s$^{-1}$ respectively for their two $z \sim 6$ galaxies. The small shifts in our galaxies are particularly significant given that in general objects with low Ly$\alpha$ emission have larger velocity offsets. A similar tentative evidence for smaller Ly$\alpha$ velocities at $z \sim 7$ compared to $z \sim 3$ was recently reported by Stark et al. (2015) using the UV nebular [CII]1909 doublet to determine the systemic redshift in two distant LBGs.

The velocity of Ly$\alpha$ compared to the systemic redshift is very relevant when interpreting the line visibility during the reionization epoch, in the presence of a partly neutral IGM

Figure 2. Maps of the [CII] emission for COSMOS13679 (upper-left), NTTDF6345 (upper-right), UDS16291 (lower-left) and COSMOS24108 (lower-right). Contours are -2, 2, 3, 4σ level. The crosses indicate the position of the near-IR detections. In the insets we show the near-IR images with ALMA contours overlayed.

(Dijkstra et al. 2011). Smaller velocity offsets imply that Ly$\alpha$ is closer to resonance and more easily quenched by a neutral IGM. If at redshift 6 and 7 the offsets are as large as those found for lower redshift LBGs, the IGM must be very neutral to produce the drop in Ly$\alpha$ fraction that is observed between these two epochs (Pentericci et al. 2014). On the other hand, if the velocity offsets were much smaller, as our observations indicate, the drop in the Ly$\alpha$ visibility could be produced by an IGM that is still substantially more ionized (Mesinger et al. 2015).

4.2. SFR-L$\text{[CII]}$ relation

In Figure 3 we show the SFR-L$\text{[CII]}$ relation for our galaxies and previously observed sources. We plot COSMOS24108 with a different symbol because it is not certain whether its [CII] emission is from the main galaxy or just from a clump in its outskirts, in which case the point would shift $\sim 1$ dex to the left. We remark that the SFR for our sources as well as previous $z \sim 7$ ones are UV-based, with no correction for dust extinction. As stated above the upper limits on the $SFR_{\text{dust}}$ are very low, at least for our galaxies. The SFR for the Capak et al. (2015) sample include both the UV and dust obscured contribution. Finally for the Willot et al. sample we plot SED-derived SFR. Our galaxies are a factor of 2-3 less luminous in
L[CII] than $z \sim 5.5$ galaxies with similar SFRs. They also fall below the SFR-L[CII] relation of low redshift star forming galaxies and low metallicity galaxies (black solid and dashed lines [De Looze et al. 2014]).

Previous observations of $z \sim 7$ galaxies failed to detect the [CII] emission. Some of the galaxies were fainter than ours, but few others were in the same range and in these cases the limits reached were deep enough to detect [CII] if the emission was at the same level as in our sources (Maiolino et al. 2015, Schaerer et al. 2015).

However we note that previously observed sources were either selected as Lyα emitters or were LBGs but their spectra showed a Lyα emission with very high EW (typically $>40 \, \AA$). The only exception z8-GND-5296 at $z=7.5$ which has modest Lyα emission, but in this case the L[CII] limit is very shallow (Schaerer et al. 2015). Our four new sources have Lyα emission with low EW (Table 1). The Lyα emission strength is known to depend on the presence on dust and possibly metallicity [Raiter et al. 2010]: although the derivation of metallicity is not easy, several studies indicate that LAEs are more metal poor galaxies compared to the rest of the LBG population (e.g. Song et al. 2014). Metallicity plays an important role in shaping the SFR-L[CII] relation: in Figure 3 we show different metallicity dependent relations produced by a recent study of Vallini et al. (2015) based on high-resolution, radiative transfer cosmological simulations. The different lines have $Z=0.05,0.1$ and $0.2 \, Z_\odot$ respectively, and for metallicity $\leq 0.1$ are consistently below the relation found for local galaxies. Therefore the contradictory results for $z \sim 7$ galaxies might be due to different intrinsic metallicity.

Alternatively galaxies could be caught in different evolutionary stages: it has been suggested that molecular clouds in the central parts of primordial galaxies could be rapidly disrupted by stellar feedback hence suppressing the emission of [CII]. Clumps of neutral gas (or small satellites) in the outer regions of such galaxies, could survive photo-ionization and still show [CII] emission, as a consequence of the diffuse far-UV emission with very high EW (typically $>40 \, \AA$).

The only exception is the empty circle indicating COSMOS24108 for which the association between the [CII] emission and the optical galaxy is uncertain. Red circles are previous $z \sim 7$ objects (Schaerer et al. 2014; Maiolino et al. 2015). Empty black squares are $z \sim 5.5$ galaxies from Capak et al. (2015); green squares are $z \sim 6$ objects from Willott et al. (2015). The black lines show the relations for local star forming galaxies and star-bursts (not-including ULIRGs) (solid) and low redshift metal poor dwarf galaxies (dashed) (De Looze et al. 2014). The red dot-dashed lines are the resulting relations from simulations [Vallini et al. 2015] for $Z=0.05Z_\odot, 0.1Z_\odot$, and $0.2Z_\odot$ respectively.

4.3. Dynamical masses

Assuming the sources have ordered motions, we can estimate the dynamical masses based on the [CII] velocity dispersion. We follow the method described in Wang et al. (2013) who approximate $M_{dyn} = 1.16 \times 10^8 V_{200}^2 D$, where $V_{200}$ is the circular velocity in km s$^{-1}$, $D$ is the size in kpc, $V_{200} = 1.763 \sigma([CII])/\sin(i)$, and $i$, the disk inclination angle. Our sources are only marginally resolved so we assume an upper limit on $D$ from the resolution of 0.9″. We obtain masses between $0.7 \times 18 \times 10^8 M_\odot$. We can compare these values to the total stellar masses determined by a classical SED fitting of the multi-wavelength photometry for the 3 CANDELS sources. We use the photometry from the CANDELS catalogs, including deep IRAC data essential for sampling the rest-frame optical emission at these redshifts. We include the contribution from nebular emission lines, which can strongly contaminate the IRAC bands. The stellar masses are reported in Table 1 and are very similar to the dynamical masses, especially considering the uncertainty due to the unknown inclination angle $i$.

5. CONCLUSIONS

We have presented ALMA [CII] emission line detections in four $z \sim 7$ galaxies. Our observations demonstrate that it is possible to detect [CII] during the reionization epoch and that the line luminosity is $\sim 3$ times lower than expected on the basis of the lower redshift relations. We find evidence for reduced velocity offsets of the Lyα emission compared to $z \sim 3$ LBGs: if confirmed this could have important implications for reionization models, since small shifts alleviate the need for a very neutral IGM to reproduce the observed decline of Lyα emission at $z \sim 7$. These results can help us tune future ALMA observations of high-z LBGs where no Lyα emission is visible but where precise photometric redshifts exist, as in the CANDELS fields. Given that in the reionization epoch most galaxies do not show Lyα emission, this means that [CII] can be an efficient alternative to derive the redshift for the majority of the galaxy population. While larger samples of targets with different luminosities and Lyα properties are needed to put our conclusions on firmer grounds, additional diagnostic can be used to interpret the physical conditions in these objects. For example in case of photo-ionization feedback [NII] at 205μm can be much stronger than [CII] (Pavesi et al. 2016). Alternatively the [OII] line at 88μm could be brighter than [CII] in chemically unevolved systems (Cormier et al. 2015) as recently observed in a dust-poor galaxy at $z=7.2$ (Inoue et al. 2016).
