(for the Hadron Spectrum Collaboration)

We present preliminary calculations towards radiative transitions in charmonium using anisotropic $N_f = 2 + 1$ dynamical ensembles generated by the Hadron Spectrum Collaboration. With the use of newer technologies we aim to investigate transitions between states, including potential exotic charmonium states, lying higher in the spectrum than in previous studies. A crucial ingredient in this work is the use of variationally optimised interpolating operators which allow for a reliable determination of the three-point correlation functions needed. Using these operators, we perform first calculations of relevant three-point correlation functions before discussing future directions.

34th annual International Symposium on Lattice Field Theory

24-30 July 2016

University of Southampton, UK

*Speaker.

1. Introduction

Lattice calculations of hadronic spectra have long been the definitive way of testing the validity of the theory of quantum chromodynamics in the non-perturbative regime. The comparison of high-precision spectral calculations with up to date experimental data allows for a rigorous test of the theory's description of the strong interaction. The accurate description of the energies of low lying states in the QCD spectrum has been an important benchmark of lattice studies for many years. Recently newer technologies and increased computational power have allowed for studies of higher-lying states and resonances. These studies allow for much more precise determinations than ever before, as well as providing valuable insight into previously unstudied regions such as hybrid or exotic states. In particular for charmonium and charmed mesons see Refs. [1, 2, 3].

Charmonium, frequently characterised as the “hydrogen atom” of meson spectroscopy due to the fact that it is non-relativistic enough to be reasonably well described by certain potential models, is the perfect testing ground for a comparison of theory with experiment. Over the last decade there has been a renewed interest in spectral calculations due to the experimental discovery of many unexpected states. Specifically in the case of charmonium, so-called X, Y, Z states highlight the need for a more complete theoretical understanding of the hadronic spectrum, be they hybrid mesons, tetra-quarks or some other hitherto unknown form of matter. Similarly, in the charm-light sector, states such as the $D_{s0}(2317)^\pm$ and $D_{s1}(2460)^\pm$ have been found to have much narrower widths than expected. For recent reviews of these topics see [4, 5].

To accurately understand the spectrum we must also investigate properties other than masses, such as decay rates. In the charmonium system the lowest-lying states lie below the $D\bar{D}$ threshold, resulting in relatively narrow widths due to the absence of OZI allowed strong decays. This means that radiative transitions, transitions from an initial state to final state via the emission of a photon, can have significant experimentally accessible branching ratios, and lattice calculations of such quantities can go a long way to provide valuable insight for experiment.

As an example, an investigation of these transition rates, through calculations of electromagnetic vector current matrix elements, gives access to a hadron's photocoupling as well as it's underlying quark and charge distributions. Calculations of this photocoupling, a measure of how strongly the hadron couples to the photon, would be of particular interest to experimentalists as a test of the expectation that the photoproduction rate of hybrid states is large.

In these proceedings we will discuss the technologies to be used to probe these transitions on dynamical ensembles, first introduced in a recent calculation of radiative transitions in the light sector in Ref. [6], with the ultimate aim of studying transitions between excited states in the charmonium spectrum. There have been some investigations into lower lying transitions, such as those seen in references [7, 8, 9, 10]. However this will be the first dynamical calculation of excited charmonium transitions using the Hadron Spectrum Collaboration's approach. Previous studies of radiative transitions in charmonium on quenched lattices can be seen in Ref. [11].

2. Techonology

We are interested in calculating quark-field vector current matrix elements between states m and n of the form $\langle m | j^\mu | n \rangle$ where j^μ is the standard vector current. These matrix elements encode, to

Lattice Volume	M_π (MeV)	N_{cfgs}	N_{tsrcs}	N_{vecs}
$20^3 \times 128$	391	50	1	128

Table 1: Information on the lattice gauge field ensemble used in this preliminary analysis, where M_π is the pion mass, N_{cfgs} and N_{tsrcs} are the number of gauge field configurations and time-sources per configuration and N_{vecs} is the number of eigenvectors used in the distillation framework.

leading order in α_{em} , the coupling of mesons and baryons to the photon. For our analysis we have $j^\mu = \frac{2}{3}\bar{c}\gamma^\mu c$, where $\frac{2}{3}$ is the charm quark charge in units of e .

Due to constraints from Lorentz invariance, these matrix elements between a hadron h of spin J and helicity λ along \vec{p} , and a second hadron h' with J', λ', \vec{p}' can be expanded as a sum over multiple form factors and Lorentz kinematic factors K_i , as discussed in Ref. [6],

$$\langle h'_{J'}(\lambda', \vec{p}') | j^\mu | h_J(\lambda, \vec{p}) \rangle = \sum_i K_i^\mu [h'_{J'}(\lambda', \vec{p}'); h_J(\lambda, \vec{p})] F_i(Q^2). \quad (2.1)$$

If the initial and final state hadrons are the same we extract the radiative form-factors $F_i(Q^2)$, where the photon's virtuality, $Q^2 = -q^2 = |\vec{p}' - \vec{p}|^2 - (E_{h'}(\vec{p}') - E_h(\vec{p}))^2$, measures the extent to which the photon is off shell. Transition form-factors are similarly extracted from matrix elements between different initial and final states.

Technically, in the case of charmonium, we do not have radiative form-factors as hidden-charm mesons are eigenstates of charge-conjugation. The physical interpretation of this is that the photon couples equally to both the quark and anti-quark in the meson. In our analysis we choose to couple only to the quark, allowing us to probe the vector current's distribution as a function of virtuality within the meson.

2.1 Optimised operators and spectroscopy

The key ingredient in any lattice spectroscopic calculation is the two-point function

$$C_{ij}(t) = \langle 0 | \mathbb{O}_i(t) \mathbb{O}_j^\dagger(0) | 0 \rangle. \quad (2.2)$$

Using the distillation framework [12], we compute correlation functions for a large basis of operators \mathbb{O}_i , and diagonalize $C_{ij}(t)$ by solving the generalized eigenvalue problem (GEVP),

$$C_{ij}(t)v^{(n)} = \lambda_n(t, t_0)C_{ij}(t_0)v^{(n)}, \quad (2.3)$$

for a carefully chosen reference timeslice t_0 . From this we extract the generalised eigenvalues λ_n and the generalised eigenvectors $v^{(n)}$, which are related to spectroscopic quantities of interest. In the construction of these correlation functions all of the interpolators used are of the form

$$\mathbb{O}_{\Lambda, \mu}^{[J, P, |\lambda|]}(\vec{p}) = \sum_{\hat{\lambda}=\pm|\lambda|} S_{\Lambda, \mu}^{\hat{\eta}, \hat{\lambda}} \mathbb{O}^{JP, \hat{\lambda}}(\vec{p}). \quad (2.4)$$

These operators, with momentum \vec{p} , have been subduced into the appropriate irreducible representations, Λ , and row μ , of the lattice symmetry group using the subductions coefficients $S_{\Lambda, \mu}^{\hat{\eta}, \hat{\lambda}}$, where

Figure 1: $e^{m_{\eta_c} t} / 2m_{\eta_c} \langle 0 | \mathcal{O}(t) \mathcal{O}^\dagger(0) | 0 \rangle$ plotted for the η_c at rest using the optimised η_c -like operator (shown in red) and the standard $\bar{\psi} \gamma_5 \psi$ operator (in black). The earlier plateau in the case of optimised operators can be seen clearly.

$\tilde{\eta} \equiv P(-1)^J$. The helicity operators, $\mathbb{O}^{J,\lambda}$, with continuum spin J , parity P and helicity λ are of the form

$$\mathbb{O}^{J,\lambda}(\vec{p}) = \sum_M D_{M\lambda}^{(J)*}(R) \mathcal{O}^{J,M}(\vec{p}). \quad (2.5)$$

Here D is a Wigner- D matrix and R is the (active) transformation that rotates $(0, 0, |\vec{p}|)$ to \vec{p} . $\mathcal{O}^{J,M} \sim CGs(m_1, m_2, m_3, \dots) \sum_{\vec{x}} e^{i\vec{p}\cdot\vec{x}} \bar{\psi}(\vec{x}, t) \Gamma_{m_1} \overleftrightarrow{D}_{m_2} \overleftrightarrow{D}_{m_3} \dots \psi(\vec{x}, t)$ is a fermion bilinear operator with spin J and spin z -component M , formed by coupling together vector-like gamma matrices Γ and gauge-covariant derivatives \overleftrightarrow{D} with the appropriate Clebsch Gordan coefficients. $\psi(\vec{x}, t)$ are the distillation smeared quark fields. For more information on these operator constructions, and a discussion on the zero momentum case, see Refs. [13, 14].

In general, each of these operators will have some overlap with each state having the same quantum numbers. It is known that some linear combination of operators in the basis will overlap most strongly onto the desired eigenstates. It can be shown that the best estimates for the weights of this linear combination (in a variational sense) come from solving the GEVP, [15], motivating the formation of *optimised operators* as

$$\Omega_{n,\Lambda,\mu}^{[J,P,|\lambda]^\dagger}(\vec{p}) = \sqrt{2E_n} e^{-E_n t_0/2} \sum_i v_i^{(n)} \mathbb{O}_{i,\Lambda,\mu}^{[J,P,|\lambda]^\dagger}(\vec{p}), \quad (2.6)$$

with E_n being the energy of the n^{th} eigenstate. For a demonstration of the feasibility of using the GEVP method to extract multiple excited states in the charmonium spectrum, see Ref. [2].

Correlators utilising these optimised operators show a plateau a number of timeslices earlier than those using the unimproved equivalent, as seen in Figure 1. This allows for the reliable extraction of spectral information at earlier times, which is of special importance for transitions between excited states.

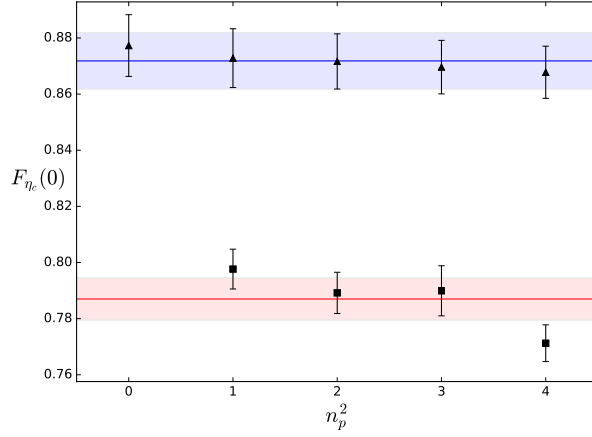

Figure 2: Preliminary value for zero momentum transfer form factor on 50 configurations. Plotted are the spatial (squares) and temporal (triangles) unrenormalised η_c form factor for different values of $n_p^2 = (\frac{L}{2\pi})^2 |\vec{p}|^2$, with the bands giving the statistical average and one sigma uncertainty.

2.2 Extracting form factors

To access matrix elements of interest in the extraction of radiative form-factors one must look at three point correlation functions, with vector current insertion j^μ

$$C_{ij}^\mu(\Delta t, t) = \langle 0 | \mathbb{O}_i(\Delta t) j^\mu(t) \mathbb{O}_j^\dagger(0) | 0 \rangle. \quad (2.7)$$

Here $\mathbb{O}_i, \mathbb{O}_j^\dagger$ are from the basis of interpolating fields and j^μ is inserted at time t such that $\Delta t > t > 0$. All operators used, as well as the vector current insertion are projected onto definite momentum. As before, these interpolators will have some overlap with all states having the same quantum numbers. The correlation functions can be expanded as

$$C_{ij}^\mu(\Delta t, t) = \sum_{m,n} \frac{1}{2E_m} \frac{1}{2E_n} e^{-E_m(\Delta t - t)} e^{-E_n t} \langle 0 | \mathbb{O}_i(0) | m \rangle \langle m | j^\mu(0) | n \rangle \langle n | \mathbb{O}_j^\dagger(0) | 0 \rangle. \quad (2.8)$$

This sum contains contamination from many excited states as well as the desired matrix element, $\langle m | j^\mu(0) | n \rangle$. Using improved interpolators which project onto the states m and n , and a normalization where $\langle n | \Omega_n^\dagger | 0 \rangle = 2E_n$ (due to Eqn. 2.6), the three point function simplifies to

$$C_{mn}^\mu(\Delta t, t) = \langle 0 | \Omega_m(\Delta t) j^\mu(t) \Omega_n^\dagger(0) | 0 \rangle = e^{-E_m(\Delta t - t)} e^{-E_n t} \langle m | j^\mu(0) | n \rangle + \dots \quad (2.9)$$

The ellipsis represents left-over contamination from higher excited states that is suppressed with the use of appropriately chosen t and Δt . The desired matrix elements are then extracted by dividing out the euclidean time dependence from the three point functions. For more information on the distillation method and the use of *generalised perambulators* in the computation of three point functions see Ref. [6].

2.3 Renormalisation and improvement of the vector current

The local vector current $\bar{\psi} \gamma^\mu \psi$, is not conserved on the lattice, and must be multiplicatively renormalised by a factor Z_V . This factor can be different for the spatial and temporal currents, Z_V^s and Z_V^t

respectively, due to the anisotropic lattice. We choose to extract Z_V from the pseudoscalar charge form-factor, $F_{\eta_c}^{lat}$, which appears in the decomposition of correlation functions with improved η_c interpolators at the source and sink for zero momentum transfer. We insist that this should take its continuum value of unity, such that

$$Z_V = \frac{F_{\eta_c}^{cont.}(0)}{F_{\eta_c}^{lat.}(0)} = \frac{1}{F_{\eta_c}^{lat.}(0)}. \quad (2.10)$$

Using improved η_c operators in the definition above we find

$$C_{\eta_c \eta_c}^\mu(\Delta t, t) = e^{-E_{\eta_c} \Delta t} \langle \eta_c | j^\mu | \eta_c \rangle, \quad (2.11)$$

up to some small pollution from higher lying states which should be minimal. This can be checked to be insignificant by varying Δt . In the case of the η_c , the decomposition of the matrix element into form factors is given as

$$\langle \eta_c | j^\mu | \eta_c \rangle = (p + p')^\mu F_{\eta_c}(Q^2). \quad (2.12)$$

As an illustrative example, when both source and sink particles have the same momenta we find, where there is no sum over μ ,

$$F_{\eta_c}(0) = \frac{1}{2p^\mu} \langle \eta_c | j^\mu | \eta_c \rangle = \frac{1}{2p^\mu} e^{E_{\eta_c} \Delta t} C_{\eta_c \eta_c}^\mu(\Delta t, t). \quad (2.13)$$

Figure 2 shows a preliminary extraction for one timesource on 50 of the available configurations of the unrenormalised zero momentum transfer η_c form factor. The difference between the temporal and spatial values extracted for F_{η_c} highlights the need for a different renormalisation factor Z_V for the temporal and spatial directions.

3. Future directions

A possible enhancement would be to use an improved current in future calculations. The anisotropic discretisation introduces a tree level $O(a)$ improvement term which amounts to replacing the Euclidean current $j_\mu = \bar{\psi} \gamma_\mu \psi$ with

$$\begin{aligned} j_0 &= Z_V^t (\bar{\psi} \gamma_0 \psi + \frac{1}{4} \frac{v_s}{\xi} (1 - \xi) a_s \partial_j (\bar{\psi} \sigma_{0j} \psi)) \\ j_k &= Z_V^s (\bar{\psi} \gamma_k \psi + \frac{1}{4} (1 - \xi) a_t \partial_0 (\bar{\psi} \sigma_{0k} \psi)), \end{aligned} \quad (3.1)$$

where $\xi = a_s/a_t$ is the anisotropy and v_s is a parameter appearing in the anisotropic fermion action. Note that a mass-dependent term has been absorbed into our renormalisation factors. As $\sigma_{\mu\nu} = \frac{i}{2} [\gamma_\mu, \gamma_\nu]$, improving the current amounts to in addition calculating correlators of the form $\langle \dots | \bar{\psi} \gamma_0 \gamma_i \psi | \dots \rangle$

In summary, we have introduced the technology needed to compute radiative transition form-factors for transitions involving excited states in the charmonium spectrum. The introduction of optimised operators which overlap strongly with a single state in the spectrum was motivated by the need to study transitions between higher excited states in the spectrum, which have been relatively unstudied up until now and will encompass the next stage of this work.
