IMPORTANCE  Because clinical features do not reliably distinguish bacterial from viral infection, many children worldwide receive unnecessary antibiotic treatment, while bacterial infection is missed in others.

OBJECTIVE  To identify a blood RNA expression signature that distinguishes bacterial from viral infection in febrile children.

DESIGN, SETTING, AND PARTICIPANTS  Febrile children presenting to participating hospitals in the United Kingdom, Spain, the Netherlands, and the United States between 2009-2013 were prospectively recruited, comprising a discovery group and validation group. Each group was classified after microbiological investigation as having definite bacterial infection, definite viral infection, or indeterminate infection. RNA expression signatures distinguishing definite bacterial from viral infection were identified in the discovery group and diagnostic performance assessed in the validation group. Additional validation was undertaken in separate studies of children with meningococcal disease (n = 24) and inflammatory diseases (n = 48) and on published gene expression datasets.

EXPOSURES  A 2-transcript RNA expression signature distinguishing bacterial infection from viral infection was evaluated against clinical and microbiological diagnosis.

MAIN OUTCOMES AND MEASURES  Definite bacterial and viral infection was confirmed by culture or molecular detection of the pathogens. Performance of the RNA signature was evaluated in the definite bacterial and viral group and in the indeterminate infection group.

RESULTS  The discovery group of 240 children (median age, 19 months; 62% male) included 52 with definite bacterial infection, of whom 36 (69%) required intensive care, and 92 with definite viral infection, of whom 32 (35%) required intensive care. Ninety-six children had indeterminate infection. Analysis of RNA expression data identified a 38-transcript signature distinguishing bacterial from viral infection. A smaller (2-transcript) signature (FAM89A and IFI44L) was identified by removing highly correlated transcripts. When this 2-transcript signature was implemented as a disease risk score in the validation group (130 children, with 23 definite bacterial, 28 definite viral, and 79 indeterminate infections; median age, 17 months; 57% male), all 23 patients with microbiologically confirmed definite bacterial infection were classified as bacterial (sensitivity, 100% [95% CI, 85%-100%]) and 27 of 28 patients with definite viral infection were classified as viral (specificity, 96.4% [95% CI, 89.3%-100%]). When applied to additional validation datasets from patients with meningococcal and inflammatory diseases, bacterial infection was identified with a sensitivity of 91.7% (95% CI, 79.2%-100%) and 90.0% (95% CI, 70.0%-100%), respectively, and with specificity of 96.0% (95% CI, 88.0%-100%) and 95.8% (95% CI, 89.6%-100%). Of the children in the indeterminate groups, 46.3% (63/136) were classified as having bacterial infection, although 94.9% (129/136) received antibiotic treatment.

CONCLUSIONS AND RELEVANCE  This study provides preliminary data regarding test accuracy of a 2-transcript host RNA signature discriminating bacterial from viral infection in febrile children. Further studies are needed in diverse groups of patients to assess accuracy and clinical utility of this test in different clinical settings.

The majority of febrile children have self-resolving viral infection, but a small proportion have life-threatening bacterial infections. Although culture of bacteria from normally sterile sites remains the gold standard for confirming bacterial infection, culture results may take several days and are frequently negative when infection resides in inaccessible sites or when antibiotics have been previously administered.\(^1\) Current practice is to admit ill-appearing febrile children to the hospital and administer parenteral antibiotics while awaiting culture results.\(^4\) \(^6\) Because only a minority of febrile children are ultimately proven to have bacterial infection, the process of ruling out bacterial infection results in a major burden on health care resources and in inappropriate antibiotic prescription.\(^7\)

Molecular tests have the potential to identify bacterial and viral pathogens and improve distinction between bacterial and viral infection.\(^8\) Rapid molecular viral diagnostics have increased the proportion of patients shown to carry respiratory pathogens,\(^9\) but viruses are frequently identified in nasopharyngeal samples from healthy children.\(^10\) Thus, detection of a virus in the nasopharynx does not rule out bacterial infection and is of little help in decisions on whether to administer antibiotics.

A number of studies have suggested that specific infections can be identified by the pattern of host genes activated during the inflammatory response.\(^11\) \(^15\) This study investigated whether bacterial infection can be distinguished from other causes of fever in children by the pattern of host genes activated or suppressed in blood in response to the infection and whether a subset of these genes could be identified as the basis for a diagnostic test.

**Methods**

**Study Conduct and Oversight**

Written informed consent was obtained from parents or guardians using locally approved research ethics committee permissions (St Mary's Research Ethics Committee (REC 09/H0712/58 and EC3263); Ethical Committee of Clinical Investigation of Galicia (CEIC ref 2010/015); UCSD Human Research Protection Program No. 140220; and Academic Medical Centre, University of Amsterdam (NL41846.018.12 and NL34230.018.10).

**Discovery and Validation Groups**

The overall design of the study is shown in Figure 1, Figure 2, and Figure 3.

Clinical data and samples were identified only by study number. Assignment of patients to clinical groups was made by consensus of 2 clinicians independent of those managing the patient, after review of investigation results using previously agreed-on definitions (Figure 2). Patients were recruited prospectively as part of a UK National Institute of Health Research-supported study (NIHR ID 8209), the Immunopathology of Respiratory, Inflammatory and Infectious Disease Study (IRIS), which recruited children at 3 UK hospitals; patients also were recruited in Spain (GENDRES network, Santiago de Compostela), and the United States (Rady Children’s Hospital, San Diego). Inclusion criteria were fever (axillary temperature ≥38°C) and perceived illness of sufficient severity to warrant blood testing in children younger than 17 years. Patients with comorbidities likely to affect gene expression (bone marrow transplant, immunodeficiency, or immunosuppressive treatment) were excluded. Blood samples for RNA analysis were collected together with clinical blood tests at, or as close as possible to, presentation to hospital, irrespective of antibiotic use at the time of collection.

**Diagnostic Process**

All patients underwent routine investigations as part of clinical care, including complete blood cell count and differential, C-reactive protein level, blood chemistries, blood and urine cultures, and cerebrospinal fluid analysis where indicated. Throat swabs were cultured for bacteria, and viral diagnostics undertaken on nasopharyngeal aspirates using multiplex polymerase chain reaction for common respiratory viruses. Chest radiographs were undertaken as clinically indicated. Patients were assigned to diagnostic groups using predefined criteria (Figure 2). The definite bacterial infection group included only patients with culture-confirmed infection, and the definite viral infection group included only patients with culture, molecular, or immunofluorescent test–confirmed viral infection and no features of coexisting bacterial infection. Children in whom definitive diagnosis was not established (indeterminate infection) were categorized into probable bacterial infection, unknown bacterial or viral infection, and probable viral infection.

**Findings**

In this cross-sectional study that included 370 febrile children, those with bacterial infection were distinguished from those with viral infection with a sensitivity in the validation group of 100% (95% CI, 85%-100%) and specificity of 96.4% (95% CI, 89.3%-100%), using a 2-transcript signature.

**Key Points**

**Question** Can febrile children with bacterial infection be distinguished from those with viral infection and other common causes of fever using whole-blood gene expression profiling?

**Findings** In this cross-sectional study that included 370 febrile children, those with bacterial infection were distinguished from those with viral infection with a sensitivity in the validation group of 100% (95% CI, 85%-100%) and specificity of 96.4% (95% CI, 89.3%-100%), using a 2-transcript signature.

**Meaning** This study provides preliminary data on the performance of a 2-transcript host RNA signature for discriminating bacterial from viral infection in febrile children. Further studies are needed in diverse groups of patients to assess accuracy and clinical utility of this test in different clinical settings.

**Patient recruitment and subsequent selection for microarray analysis.** DB indicates definite bacterial; DV, definite viral; HC, healthy control; HSP, Henoch-Schönlein purpura; JIA, juvenile idiopathic arthritis; PB, probable bacterial; PV, probable viral; SLE, systemic lupus erythematosus; U, unknown. *Controls not used for signature discovery; †Controls not used for signature validation; ‡Definite meningococcal disease.
Detection of virus did not prevent inclusion in the definite bacterial, probable bacterial, or unknown infection groups, because bacterial infection can occur in children co-infected with viruses.

**Peripheral Blood Gene Expression by Microarray**
Whole blood was collected into PAXgene blood RNA tubes (PreAnalytiX), frozen, and later extracted. Gene expression was analyzed on Illumina microarrays. Additional details of microarray method, quality control, and analysis are provided in the eAppendix (eMethods, eStatistical Methods, and eFigure 1 in the Supplement).

**Statistical Analysis**

**Transcript Signature Discovery**
Expression data were analyzed using R version 3.1.2 (R Project for Statistical Computing). Patients with definite bacterial or viral infection in the discovery group were randomly assigned to training and test sets (80% and 20% of the patients, respectively), and significantly differentially expressed transcripts distinguishing definite bacterial infection from definite viral infection were identified in the training set (Figure 3). A linear model was fitted conditional on recruitment site, and moderated t statistics were calculated for each transcript. The $P$ values obtained were corrected for multiple testing using the Benjamin-Hochberg false discovery rate method. Logistic regression with variable selection was applied to the significantly differentially expressed transcripts (absolute log$_2$-fold change $>$1 and 2-sided $P < .05$) using elastic net (a variable selection algorithm that selects sparse diagnostic transcript signatures—see eMethods and eFigure 2 in the Supplement) to further reduce the number of transcripts in the diagnostic signatures, a novel variable selection method was used that eliminates highly correlated transcripts: forward selection-partial least squares (see eAppendix in the Supplement). The disease risk score (DRS) method was applied to the resulting minimal multitranscript signature to translate it into a single value that could be assigned to each individual, to form the basis of a simple diagnostic test. The DRS method calculates a patient score by adding the total intensity of the upregulated transcripts (relative to comparator group) and subtracting the total intensity of the downregulated transcripts (relative to comparator group). The signatures identified in the discovery group were externally validated on previously published validation groups, additional patient groups with meningococcal disease and inflammatory diseases, and published datasets (3 pediatric, 1 adult) (Figure 3).

To evaluate the predictive accuracy of the DRS and of models derived after variable selection analysis, point and interval metrics were calculated using the pROC package in R. Results obtained using elastic net and DRS models were compared with reference-standard clinically assigned diagnoses (Figure 2). The area under the receiver operating characteristic

**Note:**

To evaluate the predictive accuracy of the DRS and of models derived after variable selection analysis, point and interval metrics were calculated using the pROC package in R. Results obtained using elastic net and DRS models were compared with reference-standard clinically assigned diagnoses (Figure 2). The area under the receiver operating characteristic
curve (AUC), sensitivity, and specificity were reported. Confidence intervals (95%) were calculated to measure the reliability of estimates.

Results

Two hundred forty patients (median age, 19 months; 62% male) were recruited to the discovery group between 2009-2013 in the United Kingdom (189 patients), Spain (16), and the United States (35). The definite bacterial infection group included 52 patients, of whom 36 (69%) required intensive care and 10 died. In the definite viral infection group of 92 patients, 32 (35%) required intensive care and none died (Table 1). The patients with bacterial and viral infection were subdivided into 80% (training set) and 20% (test set) (Figure 1 and Figure 3). The test set also included 96 children whose infection was not definitively diagnosed (indeterminate infection) (Figure 1 and Figure 3). The validation groups comprised 130 UK and Spanish children (median age, 17 months; 57% male) previously recruited 13 (IRIS validation; 23 with definite bacterial infection, 28 with definite viral infection, and 79 with indeterminate infection) and 72 additional validation children—25 from the United Kingdom, 30 from the Netherlands, and 17 from the United States (24 with meningococcal infection, 30 with juvenile idiopathic arthritis, and 18 with Henoch-Schönlein purpura).

The indeterminate infection group in the validation group comprised 17 probable bacterial, 55 unknown bacterial or viral, and 7 probable viral infections.

b Self-reported.

c Maximum value of C-reactive protein in illness is reported.

d Denominator denotes number of patients with viral investigations.

Identification of Minimal Transcript Signatures

Of the 8565 transcripts differentially expressed between bacterial and viral infections, 285 were identified as potential biomarkers after applying filters based on log fold change and statistical significance (see Methods). Variable selection using elastic net identified 38 transcripts (eTable 3 in the Supplement) as best discriminators of bacterial and viral infection in the discovery test set, with sensitivity of 100% (95% CI, 69%-100%) and specificity of 95% (95% CI, 84%-100%) (eTable 4 in the Supplement). In the validation group, this signature had an AUC of 98% (95% CI, 94%-100%), sensitivity of 100% (95% CI, 85%-100%), and specificity of 86% (95% CI, 71%-96%) for distinguishing bacterial from viral infection (eTable 4 and eFigures 2 and 3 in the Supplement). The putative function of the 38 transcripts in our signature, as defined by gene ontology, is shown in eTable 5 in the Supplement.

After using the novel forward selection process to remove highly correlated transcripts, a 2-transcript signature was identified that distinguished bacterial from viral infections, including interferon-induced protein 44-like (IFI44L, RefSeq NM_006820.1), and family with sequence similarity 89, member A (FAM89A, RefSeq NM_198552.1). Both transcripts were included in the 38-transcript signature.

Implementation of a DRS

The expression data of both genes in the signature was combined into a single DRS for each patient, using the reported DRS method, which simplifies application of multitranscript signatures as a diagnostic test.21 The sensitivity of the DRS was 86% (95% CI, 74%-95%) in the discovery group training set, 90% (95% CI, 70%-100%) in the discovery group test set, and 100% (95% CI, 85%-100%) in the validation data; specificity in the validation data was 96.4% (95% CI, 89.3%-100%) (Figure 4, panels A-D; eFigure 4 and eTable 4 in the Supplement). Expression of IFI44L was increased in patients with viral infection and FAM89A was increased in patients with bacterial infection, relative to healthy children (eTable 3 in
For additional validation, the 2-transcript signature was applied to patients with meningococcal disease (eFigure 6 in the Supplement) and inflammatory diseases (juvenile idiopathic arthritis and Henoch-Schönlein purpura). Bacterial infection was identified with a sensitivity of 91.7% (95% CI, 79.2%-100%) for patients with meningococcal disease and 90.0% (95% CI, 70.0%-100%) for those with inflammatory diseases and with a specificity of 96.0% (95% CI, 88.0%-100%) and 95.8% (95% CI, 89.6%-100%), respectively. When applied to 4 published datasets for children and adults with bacterial or viral infection and inflammatory disease (pediatric systemic lupus erythematosus),12,15,17,18 the 2-transcript signature distinguished bacterial infection from viral infection in all these datasets, with AUCs ranging from 89.2% to 96.6% (eTable 6 and eFigures 7 and 8 in the Supplement).

**Effect of Viral and Bacterial Co-infection**

The effect of viral co-infection on the signatures was investigated (Table 1). In the definite bacterial infection group, 30 of 47 patients tested (64%) had a virus isolated from nasopharyngeal samples. There was no significant difference in DRS between those with and without viral co-infection.

**DRS in Patients With Indeterminate Infection Status**

The classification performance of the DRS was investigated in patients with indeterminate viral or bacterial infection status. Patients were separated into those with clinical features strongly suggestive of bacterial infection (probable bacterial infection group), those with features consistent with either bacterial or viral infection (unknown infection group), and those with clinical features and results suggestive of viral infection (probable viral infection group) (Figure 2). The probable bacterial and unknown infection groups included patients with DRS values that indicated...

Abbreviation: DRS, disease risk score.

* Comparison of the proportion of patients in the combined discovery group test set and validation group receiving antibiotics, and the proportion of predicted bacterial, as predicted by the DRS (the combined IFI44L and FAM89A expression values).

The study recruited a high proportion of seriously ill patients needing intensive care, thus raising concern that selection bias...
might have influenced performance of the signature. To exclude bias based on severity or duration of illness, performance of the DRS was evaluated after stratification of patients into those with milder illness or severe illness requiring intensive care and by duration of reported illness before presentation. The DRS distinguished bacterial from viral infection in both severe and milder groups (eFigure 9 in the Supplement) and irrespective of day of illness (eFigure 10 in the Supplement).

Discussion

This study identified a host whole blood RNA transcriptomic signature that distinguished bacterial from viral infection with 2 gene transcripts. The signature also distinguished bacterial infection from childhood inflammatory diseases, systemic lupus erythematosus, juvenile idiopathic arthritis, and Henoch-Schönlein purpura and discriminated bacterial from viral infection in published adult studies.\(^\text{12,15,17,18}\) The results extend previous studies suggesting that bacterial and viral infections have different signatures.\(^\text{12,17,23}\)

The transcripts identified in the 38-transcript elastic net signature comprise a combination of transcripts up-regulated by viruses or by bacteria. The 2 transcripts \(IFN44L\) and \(FAM89A4\) in the smaller signature show reciprocal expression in viral and bacterial infection. \(IFN44L\) has been reported to be up-regulated in antiviral responses mediated by type I interferons.\(^\text{24}\) and \(FAM89A\) was reported as elevated in children with septic shock.\(^\text{25}\)

An obstacle in the development of improved tests to distinguish bacterial from viral infection is the lack of a reference standard. Some studies include patients with clinically diagnosed bacterial infection who have features of bacterial infection but whose cultures remain negative. Negative cultures may reflect prior antibiotic use, low numbers of bacteria, or inaccessible sites of infection. If patients with indeterminate status are included in biomarker discovery, there is a risk that the identified biomarker will not be specific for true infection. This study adopted the rigorous approach of identifying the signature in culture-confirmed cases and using the signature to explore likely proportions of true infection in the indeterminate infection group.

The proportion of children predicted by DRS signature to have bacterial infection follows the level of clinical suspicion (greater in the probable bacterial infection group and less in the probable viral infection group), thus supporting the hypothesis that the signatures may be an indication of the true proportion of bacterial infection in each group. Furthermore, a higher proportion of patients in the indeterminate infection group, assigned as bacterial by the signature (probable infection and unknown infection groups), had clinical features normally associated with severe bacterial infection, including increased need for intensive care, higher neutrophil counts, and higher CRP levels, suggesting that the signature may be providing additional clues to the presence of bacterial infection.

The decision to initiate antibiotics in febrile children is largely driven by concern about missing bacterial infection. A test that correctly distinguishes children with bacterial infection from those with viral infections would reduce inappropriate antibiotic prescription and investigation. The DRS suggests that many children who were prescribed antibiotics did not have a bacterial illness. If the score reflects the true likelihood of bacterial infection, its implementation could reduce unnecessary investigation, hospitalization, and treatment with antibiotics. Confirmation that the DRS provides an accurate estimate of bacterial infection in the large group of patients with negative cultures, for whom there is no reference standard, can only be achieved in prospective clinical trials. Careful consideration will be needed to design an ethically acceptable and safe trial in which observation without antibiotic administration is undertaken for febrile children suggested by DRS to be at low risk of bacterial infection.

In comparison with the high frequency of common viral infections in febrile children presenting to health care, inflammatory and vasculitic illness are very rare.\(^\text{26-29}\) However, children presenting with inflammatory or vasculitic conditions commonly undergo extensive investigation to exclude bacterial infection and treatment with antibiotics before the correct diagnosis is made. Although children with inflammatory conditions were not included in the discovery process, the 2-transcript signature was able to distinguish bacterial infection from systemic lupus erythematosus, juvenile idiopathic arthritis, and Henoch-Schönlein purpura. Additional studies including a wider range of inflammatory diseases are needed to assess use of the signature for excluding bacterial infection in inflammatory diseases.

This study has a number of important limitations. The cross-sectional design aimed to recruit equal numbers of children with bacterial and viral infections. The numbers of children recruited thus did not reflect the usual frequency of bacterial infection in febrile children presenting to health care facilities. Further studies of a test based on the 2-transcript signature in unselected febrile children will be needed to provide information on positive and negative predictive performance of the test.

A second limitation is that validation of the signatures was undertaken in groups that included a high proportion of patients requiring intensive care, and with a relatively narrow spectrum of pathogens, which may not reflect the spectrum of infection in other settings. The signature performed well, both in patients with less severe infection and those admitted to intensive care, and performance was not influenced by duration of illness. However, further studies will be needed to evaluate the DRS signature in less severely ill patients with a wider range of infections or in settings such as emergency departments or outpatient offices. Another limitation is the use in validation of published datasets and data obtained using different microarray platforms. Although batch effects were minimized computationally, additional studies are needed in which gene expression is measured on identical platforms.

A major challenge in using transcriptomic signatures for diagnosis is the translation of multitranscript signatures into...
clinical tests suitable for use in hospital laboratories or at the bedside. The DRS signature, distinguishing viral from bacterial infections with only 2 transcripts, has potential to be translated into a clinically applicable test using current technology such as polymerase chain reaction.40 Furthermore, new methods for rapid detection of nucleic acids, including nanoparticles and electrical impedance, have potential for low-cost, rapid analysis of multitranscript signatures.

ARTICLE INFORMATION
Correction: This article was corrected online on February 7, 2017, for errors in the text, Figure 1, and the online Supplement.

Author Affiliations: Section of Paediatrics, Division of Infectious Diseases, Department of Medicine, Imperial College London, London, United Kingdom (Herberg, Kafourou, Wright, Shailas, Eleftherhorinou, Hoggart, Carter, Janes, Gормley, Levin); Translational Paediatrics and Infectious Diseases Section, Department of Paediatrics, Hospital Clínico Universitario de Santiago, Santiago de Compostela, Galicia, Spain (Cobeý-López, Salas, Martinón-Torres); Grupo de Investigación en Genética, Vacunas, Infecciones y Pediatría (GENVIP), Healthcare Research Institute of Santiago de Compostela and Universidade de Santiago de Compostela, Spain (Cobeý-López, Salas, Martín-Torres); Department of Pediatrics, University of California San Diego, La Jolla (Shimizu, Tremoulet, Kanegaye, Burns); Rady Children’s Hospital San Diego, San Diego, California (Shimizu, Tremoulet, Kanegaye, Burns); Emma Children’s Hospital, Department of Paediatric Haematology, Immunology and Infectious Diseases, Academic Medical Centre, University of Amsterdam, Amsterdam, the Netherlands (Barendregt, Kuipers); Unidade de Xenética, Departamento de Anatomía Patológica e Ciencias Forenses, and Instituto de Ciencias Forenses, Grupo de Medicina Xenómica, Spain (Salas); Department of Paediatrics, University of Oxford, Oxford, United Kingdom (Pollard); National Institute of Health Research Oxford Biomedical Research Centre, Oxford, United Kingdom (Pollard); National Institute of Health Research Wellcome Trust Clinical Research Facility, University of Southampton, Southampton, United Kingdom (Faust); University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom (Faust, Patell); Sanquin Research and Landsteiner Laboratory, Amsterdam Medical Centre, Department of Blood Cell Research, University of Amsterdam, Amsterdam, the Netherlands (Kuipers); Institute for Molecular Bioscience, University of Queensland, St Lucia, Queensland, Australia (Coim).

Author Contributions: Drs Herberg and Levin had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. Drs Herberg, Kafourou, and Wright contributed equally to this work.

Concept and design: Herberg, Kafourou, Wright, Adiefeherhorinou, Hoggart, Carter, Janes, Barendregt, Levin.

Obtaining funding: Herberg, Kafourou, Wright, Tremoulet, Barendregt, Kuipers, Burns, Levin.

Conflict of Interest Disclosures: All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Dr Kanegaye reported receiving a grant from the Gordon and Marilyn Macklin Foundation. Dr Faust reported receiving research nursing support from the National Institute of Health Research Clinical Research Network; and grants from Pfizer, Sanofi, GlaxoSmithKline, Novartis, Allos, and Alnyrx. Dr Coin reported holding a patent pending for disease risk score methodology. Dr Levin reported preparing a patent application for the 2-gene signature used in this study. No other authors reported disclosures.

Funding/Support: This work was supported by the Imperial College Comprehensive Biomedical Research Centre (DMPED P26077); National Institute of Health Research (NIHR) Senior Investigator award (Dr Levin); Great Ormond St Hospital Charity (V1401; Dr Wright); European Union’s Seventh Framework Program (EC-GA 279185) (EUCUDS) (Dr Herberg); Imperial College-Wellcome Trust Antimicrobial Research Collaborative (ARC) Early Career Fellowship (RSRO 594990) (Dr Kafourou); Spanish Research Program (FIS; PI10/00540 and Intensificacion actividad investigadora of National Plan I + D + I and FEDER funds) and Regional Galician funds (Promotion of Research Project 10 PXIB 918 184 14 PIR) (Dr Martinón-Torres); Southampton NIHR Wellcome Trust Clinical Research Facility and NIHR Wessex Local Clinical Research Network; and Academic Medical Centre Amsterdam MD/PHD program 2013 (Ms Barendregt). The UK meningococcal disease cohort was established with grant support from the Meningitis Research Foundation (United Kingdom); the inflammatory disease cohort was supported by a Macklin Foundation grant (Dr Burns), National Institutes of Health grant U54-HL08460 (Dr Burns); and The Hartwell Foundation and The Harold Aron Medical Faculty Development Program/Robert Wood Johnson Foundation (Dr Tremoulet).

Role of the Funders/Sponsors: The funders/ sponsors had no role in the design or conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Additional Information: People linked to the IRIS consortium through membership of the GENDRES consortium (http://www.gendres.org) are listed in the eAppendix in the Supplement.

Additional Contributions: We wish to thank the children and families who have participated in the study. Jayne Dennis, PhD (St George’s University of London), for her support and advice for the microarray experiments, Chenxi Zhou, MSc (University of Queensland), for his help with the feature selection software, and the clinical teams for their assistance in recruiting patients to the study. These persons did not receive direct compensation for their work.
