Visible-light driven H$_2$ evolution in water is achieved using catechol-photosensitised TiO$_2$ nanoparticles with a molecular nickel catalyst. Layer-by-layer immobilisation of catechol-TiO$_2$ onto tin-doped indium oxide electrodes generates photocathodic currents in the presence of an electron acceptor. This approach represents a new strategy for controlling photocurrent direction in dye-sensitised photoelectrochemical applications.

Immobilising molecular dyes onto wide band-gap metal oxide semiconductors is a well-established strategy for preparing tuneable, visible-light responsive materials from relatively inexpensive components. This approach was pioneered for solar energy conversion in dye-sensitised solar cells (DSCs) and is an emerging field in the area of solar fuels synthesis. In the majority of dye-sensitised systems, photoexcitation occurs in the dye (HOMO-LUMO transition) followed by fast charge injection into the semiconductor (Type I sensitisation, Fig. 1a). This approach has been effective in H$_2$ production using dye-sensitised photocatalysis (DSP) and in forming photoanodes for dye-sensitised photoelectrochemical cells (DSPEC); however, the translation of DSP systems to photocathodes is more challenging, often relying on low-performance p-type semiconductors (such as NIO) or molecular engineering to control the direction of electron transfer.

Charge-transfer sensitisation, in which photoexcitation occurs directly from a surface-adsorbed molecule to the semiconductor conduction band (Type II, Fig. 1a), has recently been explored as a low-cost alternative in DSCs and solar fuel production. Type II sensitisation is known to occur in TiO$_2$ functionalised with phenol and enediol groups, such as catechols. These groups bind to Ti$^{4+}$ ions on the surface of TiO$_2$, forming complexes that absorb visible light due to ligand-to-metal charge-transfer (Fig. 1b). This one-step transfer from dye to TiO$_2$ results in very fast electron injection (on the order of fs) and, importantly, by avoiding excitation into the dye LUMO the charge-transfer is inherently directional (Fig. 1a and S1). Type II sensitisation also occurs between carbon nitride and TiO$_2$, and has been used to enhance solar light-driven H$_2$ evolution with hydrogenase, and to form photoanodes for photoelectrochemical water oxidation.

Catechol-containing dyes based on alizarin red have been studied for DSP and for photocurrent switching applications; however, these dyes are also Type I sensitisers. To our knowledge, the only example of purely Type II visible-light driven H$_2$ evolution uses phenolic resin-sensitised TiO$_2$ nanoparticles, with Pt as the H$_2$ evolution catalyst (HEC) in the presence of a sacrificial electron donor (SED). Replacing noble metals with inexpensive catalysts and moving towards SED-free systems are both important goals in solar energy conversion in dye-sensitised systems, photoexcitation occurs in the dye (HOMO-LUMO transition) followed by fast charge injection into the semiconductor (Type I sensitisation, Fig. 1a). This approach has been effective in H$_2$ production using dye-sensitised photocatalysis (DSP) and in forming photoanodes for dye-sensitised photoelectrochemical cells (DSPEC); however, the translation of DSP systems to photocathodes is more challenging, often relying on low-performance p-type semiconductors (such as NIO) or molecular engineering to control the direction of electron transfer.

Charge-transfer sensitisation, in which photoexcitation occurs directly from a surface-adsorbed molecule to the semiconductor conduction band (Type II, Fig. 1a), has recently been explored as a low-cost alternative in DSCs and solar fuel production. Type II sensitisation is known to occur in TiO$_2$ functionalised with phenol and enediol groups, such as catechols. These groups bind to Ti$^{4+}$ ions on the surface of TiO$_2$, forming complexes that absorb visible light due to ligand-to-metal charge-transfer (Fig. 1b). This one-step transfer from dye to TiO$_2$ results in very fast electron injection (on the order of fs) and, importantly, by avoiding excitation into the dye LUMO the charge-transfer is inherently directional (Fig. 1a and S1). Type II sensitisation also occurs between carbon nitride and TiO$_2$, and has been used to enhance solar light-driven H$_2$ evolution with hydrogenase, and to form photoanodes for photoelectrochemical water oxidation.

Catechol-containing dyes based on alizarin red have been studied for DSP and for photocurrent switching applications; however, these dyes are also Type I sensitisers. To our knowledge, the only example of purely Type II visible-light driven H$_2$ evolution uses phenolic resin-sensitised TiO$_2$ nanoparticles, with Pt as the H$_2$ evolution catalyst (HEC) in the presence of a sacrificial electron donor (SED). Replacing noble metals with inexpensive catalysts and moving towards SED-free systems are both important goals in
achieving sustainable fuel synthesis. Here we take steps towards addressing these challenges by developing a new route for assembling noble metal-free photocathodes. First, we demonstrate that Pt can be replaced by a 3d transition metal catalyst to form an active Type II DSP system (Fig. 1c). We then develop a SED-free photoelectrochemical system, using the directionality of the charge-transfer complex to form photocathodes on a conductive electrode support (Fig. 1d).

For the DSP system, a range of charge-transfer dye-sensitised TiO$_2$ powders were prepared by mixing simple catechol derivatives (Fig. 2a) with commercial P25 TiO$_2$ nanoparticles (average crystallite size 21 nm, 8:2 mixture of anatase:rutile). The resulting coloured powders exhibited broad light absorption over the visible range (Fig. S2). The dye loadings ranged from 75 – 172 nmol (mg TiO$_2$)$^{-1}$ (Table S1). These loadings correspond to an estimated footprint of 0.5 – 1.1 nm$^2$ molecule$^{-1}$, consistent with reported ranges for submonolayer to monolayer coverage of catechols on TiO$_2$.\(^\text{11}\)

Photocatalysis solutions were prepared by suspending the dye-P25 powders (2.5 mg) in aqueous SED solution (ascorbic acid, AA, 0.1 M, 2.25 mL). We selected the HEC \(\text{Ni(php)}_3\text{N}^{+}\text{Li}^-\text{ClO}_4^-\text{Ni(Oh)}_3\text{Cl}^-\text{Br}_2\), NP (Fig 1c), as it has previously been shown to be highly active in aqueous DSP\(^\text{12}\) and DSPEC\(^\text{13}\). \(\text{NiP}\) (50 nmol) was added to the dye-P25 suspension as a solution in methanol (1 mM) before the photoreactors were purged with N$_2$ and irradiated with simulated solar light ($\lambda > 420$ nm, AM 1.5 G, 100 mW cm$^{-2}$). The formation of the hybrid DSP system (Fig 1c) is supported by FTIR and UV-vis spectroscopy (Fig S3), with an estimated NP loading of 38 nmol mg$^{-1}$ for CA-P25 (calculated using the difference in absorption at 450 nm of a NP solution before and after exposure to TiO$_2$). No H$_2$ was detected in control experiments without AA, TiO$_2$ or NP, or with NiCl$_2$ in place of NP.

AA can also sensitise TiO$_2$ through charge-transfer interactions, resulting in small amounts of H$_2$ evolution in the absence of additional catechol during visible light irradiation (Fig. 2b, “None”); however, all ex situ functionalised powders enhanced the activity compared to bare P25 (Fig 2b and S4a). The highest activity was obtained with caffeic acid (CA; Fig. 2), with a turnover number with respect to the powder (TON$_\text{P}$) of 273 $\pm$ 29 mol H$_2$ g$^{-1}$ after 4 h. The turnover frequency (TOF$_\text{P}$) of 73 $\pm$ 3 mol H$_2$ (g TiO$_2$)$^{-1}$ h$^{-1}$ was maintained over the first 4 h, equivalent to a TOF per Ni catalyst (TOF$_\text{Ni}$) of 3.6 $\pm$ 0.2 mol H$_2$ (mol NP)$^{-1}$ h$^{-1}$ and TOF per catechol of 0.6 $\pm$ 0.2 mol H$_2$ (mol CA)$^{-1}$ h$^{-1}$. This result is comparable to that reported for the phenolic resin system with Pt (105 mol g$^{-1}$ h$^{-1}$).\(^\text{6b}\) The TOF$_\text{Ni}$ is an order of magnitude lower than previously reported for the equivalent system with a Ru tris(bipyridine) dye, RuP,\(^\text{12}\) but RuP can directly reduce NP in solution, whereas the catechol derivatives cannot. The lower extinction coefficient and faster recombination rate of the charge-transfer band relative to that of metal-based dyes (psi vs. ns – $\mu$s$^{-1}$) are also expected to contribute to the difference in activity.

The high activity of CA relative to the unconjugated analogue 3,4-dihydroxyhydrocinnamic acid (DHCA) is consistent with the red-shift in the absorption spectrum and increase in both the catechol binding constant and the electron injection efficiency associated with greater conjugation.\(^\text{1b}\) The activity per dye molecule also reflects this trend for 2-(3,4-dihydroxybenzenyl)thiophene (DHBT; Fig. S4b); however, the lower loading of DHBT on TiO$_2$ compared to CA (Table S1) resulted in a lower TON$_\text{P}$ (Fig 2b). Ring conjugation (2,3-naphthalenediol, ND) did not enhance activity (Fig 2b and S4b), which is likely due to the comparatively low visible light absorption of ND-P25 (Fig. S1).

TON$_\text{Ni}$ increased with decreasing NP loading (Fig. S5a) and increasing CA-P25 powder loading (Fig. S6a). However, the corresponding TON$_\text{Ni}$ decreased with decreasing NP loading (Fig. S5b) and reached a maximum at a CA-P25 loading of 1.25 mg (Fig. S6b). Since increasing the powder loading increases both the dye loading and the particle:NI ratio, it can be inferred that the H$_2$ production rate is limited by the generation and supply of electrons to NP. This conclusion is supported by the decrease in activity of the system on decreasing the light intensity (Fig S7). The external quantum efficiency (EQE) of the most active system (5 mg CA-P25, 50 nmol NP) was measured to be 0.09 $\pm$ 0.01 %.

Since light absorption is related to the number of catechol-TiO$_2$ surface interactions, light absorption per g can be enhanced by using smaller nanoparticles to increase the surface area. We synthesised TiO$_2$ nanoparticles by a previously reported method (pure anatase, average diameter ~7 nm, AN7-TiO$_2$, see Fig S8 for TEM)\(^\text{14}\) and tested both these and commercial pure anatase nanoparticles (10 nm, AN10-TiO$_2$, Fig. S7) under the standard DSP conditions (CA-TiO$_2$, 2.5 mg, 50 nmol NP). However, despite the increase in catechol loading (505 nmol (mg TiO$_2$)$^{-1}$; Table S1) and light absorption (Fig S9) compared to P25, these particles displayed less photocatalytic activity (Fig. S10). The lower performance was not found to be due to a difference in binding of NP to the particles (48 and 51 nmol mg$^{-1}$ for AN10-TiO$_2$ and AN7-TiO$_2$).
respectively. However, it is likely that the smaller, pure anatase particles suffer from less efficient charge separation compared to the larger, mixed-phase (anatase/rutile) P25. Pure rutile phase TiO₂ nanoparticles (R-TiO₂, 10 – 30 nm) displayed lower activity than P25, AN10, and AN7-TiO₂ (4.9 ± 0.3 after 3 h, Table S2, Fig. S10).

Having established that catechol-TiO₂ hybrids are effective light absorbers for (UV−filtered) solar H₂ evolution with NiP, we sought to transfer the DSP system onto photoelectrodes. We designed a layer-by-layer route to immobilise the TiO₂ nanoparticles onto a degenerately doped n-type metal oxide support (indium tin oxide, ITO) in a directed, sequential fashion (Fig. 1d). In order to maximise the deposition of the TiO₂ nanoparticles in our system, we used hierarchical inverse opal mesoporous ITO electrodes (IO-ITO; Fig. S11a). IO-ITO is an effective support for nanoscale adsorbates such as enzymes (e.g. Photosystem II, 10.5 x 20.5 x 11.0 nm³), owing to their open, macroporous structure (750 nm pores with 150 nm interconnecting chambers) and high surface area mesoporous scaffold (formed from <50 nm ITO nanoparticles). Mesoporous ITO (mesoITO) electrodes (1 µm thickness, Fig. S11b) were also prepared for comparison.

By studying the attachment of DHCA to IO-ITO in the presence or absence of one equivalent of propylphosphonic acid by UV−vis spectroscopy, we found that ITO binds preferentially to phosphonate groups over catechol groups (83% of DHCA is displaced; Fig S12a). We therefore synthesised (E)-3,4-dihydroxystyryl)phosphonic acid (DHSP; see ESI for synthetic details) as a bifunctional, phosphonated catechol that is expected to bind to ITO in the correct orientation for subsequent formation of the charge-transfer interaction with TiO₂. In contrast to ITO, TiO₂ has an approximately equal binding affinity for catechol and phosphonic acid groups (45% of DHCA was displaced in the presence of propylphosphonic acid; Fig S12b). Therefore, formation of the charge-transfer complex was only effective if DHSP was anchored to ITO before adding TiO₂: ex situ-prepared DHSP-sensitised P25 powders did not absorb appreciably in the visible−light region.

DHSP was anchored onto ITO by incubating the electrodes in an aqueous stock solution (1 mM, 2 − 8 °C, 16 h). Cyclic voltammetry (CV) of DHSP-functionalised flat ITO shows a quasi-reversible wave (E_{1/2} = 0.84 V vs. RHE), which can be assigned to the catechol/semiquinone redox couple (Fig S13). By monitoring the change in absorbance of a stock solution of DHSP (1 mM) at 280 nm after incubation with IO-ITO electrodes, the loading of DHSP was estimated to be 64.0 ± 10.9 nmol cm⁻², which matches the loading estimated from the charge passed during CV (55.5 nmol cm⁻², see ESI).

The final charge-transfer complexes were formed by depositing TiO₂ nanoparticles onto the DHSP-functionalised ITO. In contrast to the photocatalysis results, the electrodes with the highest photocurrent in the presence of an acceptor (O₂) were those prepared with AN7-TiO₂ nanoparticles (Fig. S14). The nanoparticles were deposited by immersion of the ITO|DHSP electrodes in a stock solution of oleic acid-capped AN7-TiO₂, followed by treatment with NEt₃ (10 vol% in ethanol) to remove surface oleic acid, as confirmed by FTIR spectroscopy (Fig. S15). The formation of the charge-transfer complex was evidenced by a change in colour of the electrodes from pale yellow/green to peach (Fig. S16). The loading of TiO₂ was measured to be 212.4 µmol cm⁻² for 12 µm thick IO-ITO (Ti content; Inductively Coupled Plasma-Optical Emission Spectroscopy, ICP-OES), which corresponds to approximately 83 nmol of nanoparticles per cm².

Scanning electron microscopy (SEM) of AN7-TiO₂ on DHSP-functionalised flat ITO showed that an even monolayer of particles is formed (Fig. S17), and energy-dispersive X-ray spectroscopy (EDX) of the fully assembled IO-ITO|DHSP|AN7-TiO₂ electrodes showed that the particles are evenly distributed throughout the IO-ITO structure (Ti content of 11.8, 11.4, and 10.7 at% for the top, middle, and bottom part of the IO-ITO structure respectively; Fig. S18a). In contrast, EDX analysis of equivalent electrodes prepared with P25 TiO₂ showed that these nanoparticles do not penetrate beyond the surface (10 – 12 at% Ti detected only on the top surface and none at lower layers; Fig. S18b). The difference in particle distribution, and subsequent performance, is attributed to the better size match of the macro- and mesopores of the IO-ITO structure to the smaller, well-dispersed AN7-TiO₂ compared to the larger, aggregated P25 particles (close to micron-sized aggregates of 20 nm particles; see Fig. S8 for TEM). AN10-TiO₂ nanoparticles also form aggregates (Fig. S8), resulting in low performance (Fig. S14).

In the presence of the electron acceptor O₂, cathodic photocurrents were obtained under visible light irradiation (λ > 400 nm, 100 mw cm⁻²) with IO-ITO|DHSP|AN7-TiO₂ electrodes below the redox potential of DHSP (E_{applica} = 0.3 V vs. RHE, Fig. 3a). Initial current spikes were observed in the photocurrent curves of these electrodes (Fig 3a), which likely occur due to rapid polarisation and charge accumulation of the electrode. A switch to anodic photocurrent was observed at potentials where DHSP is oxidised (E_{applica} > +0.7 V vs. RHE, Fig. S19). The photocurrent is attributed to the formation of the charge-transfer complex since little photocurrent is obtained in the absence of the catechol and/or TiO₂ (Fig. 3a). The magnitude of the photocurrent scales with the thickness of the ITO scaffold, reflecting the increase in loading of the dye-TiO₂ complex with increasing ITO surface area (Fig. 3b). The photocurrents obtained with 12 µm thick IO-ITO (70 µA cm⁻²) are comparable to those obtained with Ru-based Type I dyes in the presence of an acceptor, demonstrating the promise of employing metal-free Type II dyes.

In the absence of O₂ (N₂ purged solution), small cathodic currents were maintained for the bare IO-ITO|DHSP|AN7-TiO₂ electrodes (Fig. S20). Although NiP could be immobilised onto the electrodes (maximum loading of 28.9 ± 2.9 nmol per cm²; UV−vis spectroscopy), photo-driven H₂ evolution was not achieved with these electrodes. It is possible that the phosphonate groups in NiP may displace either the some or all of the DHSP groups from the surface of the TiO₂. NiP can also bind directly to ITO, by-passing the dye-TiO₂ construct.

Therefore, although the layer-by-layer design successfully generates a directional, dye-sensitised electrode, further catalyst design is required in order to fully translate the DSP
system to DSPEC.

In conclusion, we have demonstrated for the first time that catechol-TiO$_2$ complexes are effective photosensitisers for driving sacrificial H$_2$ evolution with an earth-abundant molecular catalyst, forming a fully noble metal-free Type II DSP system. Using a layer-by-layer method, we have transferred the dye-sensitised TiO$_2$ to an electrode to form a Type II photocathode. The excellent size match between the hierarchical IO-ITO support and the TiO$_2$ nanoparticles is critical for high dye-TiO$_2$ loading. The obtained photocurrents with a sacrificial electron acceptor are comparable to those obtained with Type I dyes, indicating that this is a promising means to control photocurrent direction and allow the use of n-type metal oxide supports (such as ITO) in DSPEC applications. This work represents an important first step in translating functional DSP systems to DSPEC; however, challenges in coupling these electrodes to a H$_2$ evolution catalyst will need to be overcome in order to apply them for fully sustainable solar fuels synthesis.
