39

40 **ABSTRACT:** During gastrulation, cell types from all three germ layers are specified  
41 and the basic body plan is established<sup>1</sup>. However, molecular analysis of this key  
42 developmental stage has been hampered by limited cell numbers and a paucity of  
43 markers. Single cell RNA sequencing circumvents these problems, but has so far been  
44 limited to specific organ systems<sup>2</sup>. Here we report single-cell transcriptomic  
45 characterisation of over 20000 cells immediately following gastrulation at E8.25 of  
46 mouse development. We identify 20 major cell types, which frequently contain sub-  
47 structure, including three distinct signatures in early foregut cells. Pseudospace  
48 ordering of somitic progenitor cells identifies dynamic waves of transcription and  
49 candidate regulators, which are validated by molecular characterisation of spatially  
50 resolved regions of the embryo. Within the endothelial population, cells that transition  
51 from haemogenic endothelial to erythro-myeloid progenitors specifically express  
52 *Alox5* and its co-factor *Alox5ap*, which control leukotriene production. Functional  
53 assays using mouse embryonic stem cells demonstrate that leukotrienes promote  
54 haematopoietic progenitor cell generation. This comprehensive single cell map  
55 therefore can be exploited to reveal previously unrecognised pathways contributing to  
56 tissue development.

57 **Main**

58 During mouse gastrulation, epiblast cells differentiate into the three germ layers  
59 endoderm, mesoderm and ectoderm. This process is followed by rapid differentiation  
60 into organ-specific cell types so that, by embryonic day E8.25, precursor cells of  
61 major organs have been formed<sup>1</sup>. To characterise the full complement of cell types  
62 present at this stage, we collected C57BL/6 mouse embryos at E8.25, including their  
63 extraembryonic tissues. Following dissociation, embryos were pooled and processed  
64 on a 10X microfluidic chip, and the resulting libraries were sequenced on an Illumina  
65 HiSeq 2500 (Fig. 1A). Following filtering of low quality samples (Methods), 19,396  
66 cells were retained for downstream analyses. On average, 15,073 unique transcripts  
67 were captured and around 3,518 genes were detected in a typical cell (Fig. 1B).

68 Following identification of genes with highly variable expression across the  
69 dataset, we assigned cells into 33 different groups (Methods). We then used the  
70 expression of previously annotated marker genes to infer each clusters' identity. We  
71 annotated 20 major cell populations, several of which comprised two or more clusters  
72 (Fig. 1C). Cluster identification was consistent between cell populations from one  
73 sample captured on different 10X chip channels, and between two independent  
74 samples (Supplementary Fig. 1A-B). The proportions of cells from each sample were  
75 generally consistent with the expected proportions based on the overall dataset  
76 (Supplementary Table 1), suggesting that the capture rate is unbiased across  
77 experiments.

78 Next, to assess the stability of our classification, we repeated the experiment  
79 using embryos from an F2 cross of mixed genetic background (C57BL/6 and CBA).  
80 In this case we sequenced ~7,000 cells from three individual embryos. Remarkably,  
81 the results from the clustering analysis were almost identical and all major cell types

82 were identified in both datasets, except for the extraembryonic ectoderm, which was  
83 removed when dissecting the F2 embryos (Supplementary Fig. 1C-D). Thus, we  
84 conclude that we have captured the heterogeneity in cell populations present in mouse  
85 embryos of different genetic backgrounds at this stage of development.

86 We observed cell types from all three germ layers (Fig. 1C), characterised by  
87 the expression of 869, 240 and 159 genes preferentially upregulated in endodermal,  
88 mesodermal or ectodermal cells respectively (false discovery rate < 5%, fold-change  
89 > 2; Supplementary Fig. 1E; Supplementary Table 2). This included well-established  
90 markers, such as *Sox17*, *Epcam* and *Foxa1/2* for endoderm<sup>3</sup>, *Pdgfra*, *Tbx6* and  
91 *Brachyury (T)* for mesoderm<sup>4</sup> and *Sox1*, *Pax6* and *Pou3f1* for ectoderm<sup>5</sup>. We also  
92 identified germ layer specific genes that have not been described in the context of  
93 embryo development including *Gm2694* and *Mir124-2hg*, which show specific  
94 expression in ectoderm (Supplementary Fig. 1F). Furthermore, many other genes  
95 showed restricted expression to one or a few of our defined cell types (Supplementary  
96 Fig. 1E), providing valuable candidate markers for defining and potentially  
97 programming populations of cells toward specific lineages (for visualisation see  
98 <http://marionilab.cruk.cam.ac.uk/organogenesis/>).

99 Closer inspection of specific clusters revealed that most exhibited additional,  
100 subtle sub-structure. We hypothesised that such sub-structure could shed light on  
101 early regulatory processes that drive fine-grained specification of cell fate. For  
102 example, between E8.0 and E9.0 the endoderm undergoes a series of morphogenetic  
103 changes that turn it from a flat sheet into a tube where the domains of major organs  
104 like the liver and lung arise<sup>6</sup>. While ventral folding and formation of the foregut  
105 pouch is already induced at E8.25<sup>6</sup>, the earliest stages of foregut endoderm  
106 diversification remain ill-defined at the molecular level.

107 To explore this further, we considered cells in the foregut cluster (Fig. 1C) and  
108 used a diffusion map approach<sup>7</sup> to visualise three sub-clusters (Fig. 2A and  
109 Supplementary Fig. 2A). We then identified differentially expressed genes (Fig. 2B;  
110 Supplementary Table 3) and contrasted these with in situ images from the literature to  
111 assign cluster identities. The red cluster expressed markers of early endodermal cells  
112 including *Gsc*, *Trh* and *Otx2*<sup>8,9</sup>. In contrast, the blue cluster expressed *Ttr*, *Hhex* and  
113 *Tbx3*<sup>10</sup>, all markers of hepatic progenitors, while the yellow cluster was characterised  
114 by *Irx1/3/5* and *Pax9*<sup>11,12</sup>, typical of the thyroid anlage and lung specification.

115 Lineage tracing studies have followed the movement of endodermal cells in  
116 embryos from the one to ten somite stages and revealed that cells from different  
117 regions of the gut populate different organs later in development<sup>13</sup>. Our findings  
118 suggest that regionalization is also evident at the molecular level as early as the 4-  
119 somite stage. Importantly, this included potential markers of early foregut lineage  
120 specification. For example, *Hesx1* is a homeodomain transcription factor involved in  
121 the development of the forebrain and the pituitary gland<sup>14</sup>; in our data, it is restricted  
122 to the early endoderm cluster suggesting a possible role in regulating foregut  
123 development. Overall, our analysis illustrates how domain specific knowledge can be  
124 used to allocate biological identity in the context of sparse scRNA-seq data.

125 The molecular processes driving differentiation cannot be readily studied in  
126 human embryos. This poses difficulties for the validation of protocols that aim to  
127 produce authentic cell types from human induced pluripotent stem cells. We  
128 compared the transcriptome of human foregut progenitor cells – induced from human  
129 pluripotent stem cells (Methods) – to our mouse data. We used the *pairs classifier*, a  
130 classification algorithm that is robust to confounding effects due to differences in  
131 experimental protocols and normalisation<sup>15</sup>, to map the human foregut-like cell

132 samples onto our single cell endoderm atlas. All replicates were assigned a foregut  
133 identity when compared with the mouse data for fore-, mid- and hindgut (Fig. 2C and  
134 Supplementary Fig. 2B). Thus, our single cell mouse embryo dataset provides a  
135 valuable *in vivo* reference that can be used to assess the identity of *in vitro* derived  
136 cell populations.

137         As a snapshot measure, scRNA-seq data seems ill-suited to recover dynamic  
138 information on cell fate specification. However, when entry into a defined  
139 differentiation program is desynchronised across a cell sub-population, dynamic  
140 information can be recovered through the “chromatographic” segregation of the  
141 molecular profile. Motivated by this, we focused on the process of somitogenesis,  
142 which involves the segmentation of the developing embryonic body axis into somites  
143 and is guided by oscillating genes, which create waves of expression that travel across  
144 the presomitic mesoderm (PSM) from posterior to anterior<sup>16</sup> (Fig. 3A). Upon arrival  
145 of a wave at the PSM's anterior end, a new somite is formed. The posterior end of the  
146 PSM is marked by high levels of Wnt and FGF signalling while somites show high  
147 levels of retinoic acid (RA)<sup>16</sup> (Fig. 3A).

148         To explore whether coherent patterns of gene expression could be resolved  
149 from our snapshot data, we analysed the cells from the mesoderm progenitors,  
150 presomitic and somitic mesoderm clusters (Fig. 1C). We first ordered cells along a  
151 putative anteroposterior (AP) axis by using genes highly correlated with *Fgf8*, which  
152 serves as a positional landmark<sup>16</sup> (Fig. 3B). The inferred pseudo-space axis  
153 recapitulated the expected signalling gradients, from the highest expression of *Fgf8* to  
154 the highest expression of *Aldh1a2*, the synthesizing enzyme of RA (Fig. 3C). Next,  
155 we modelled gene expression along this pseudo-space axis to identify genes  
156 characterised by a localised wave-like peak within the PSM.

157           The expression profiles of a thousand genes were inconsistent with constant  
158 expression across pseudo-space (Fig. 3D; Methods); 93 of these showed wave-like  
159 expression that peaked along the pseudo-space trajectory (Fig. 3E), and included  
160 several well-known regulators of somitogenesis such as *Hes5*, *Lfng* and *Dll1*<sup>16</sup>.  
161 Indeed, when examining the expression across pseudo-space of experimentally  
162 characterised oscillating genes, most showed wave-like expression (Fig. 3G).  
163 Moreover, we identified several genes where oscillatory activity has not been reported  
164 (Fig. 3E), but that behave similarly to classic oscillating genes. One of these, *Cited1*  
165 (Fig. 3E), has been identified as being expressed within the PSM<sup>17</sup> and is known to  
166 block epithelial differentiation in the kidney<sup>18</sup>. We thus hypothesise a possible role  
167 during somitogenesis, where the interior of the somite remains mesenchymal whereas  
168 the somite boundary undergoes a mesenchymal-to-epithelial transition<sup>19</sup>.

169           To validate these findings, we dissected the PSM of four different mouse  
170 embryos – keeping the left and right sides separate – and divided each into five  
171 segments from posterior to anterior (Supplementary Fig. 3A and Supplementary  
172 Video 1). We then performed RNA sequencing on each segment, for six biological  
173 replicates. The expression dynamics across the AP axis of the 93 genes we defined as  
174 oscillatory (Fig. 3E) were well correlated to the single-cell data (median Pearson's  
175 correlation, interquartile range for all genes = 0.51-0.78; Fig. 3F and Supplementary  
176 Fig. 3B), and so were the profiles of well-characterised oscillatory genes  
177 (Supplementary Fig. 3C). Furthermore, the expression profile of *Cited1* showed a  
178 wave-like pattern in five out of the six replicates, peaking at distinct locations along  
179 the AP axis, consistent with embryo-specific wave progression (Fig. 3H). Together,  
180 these findings show that static snapshots of single cell molecular profiles provide a

181 promising strategy to identify candidate genes that contribute to developmental  
182 processes driven by oscillatory gene expression.

183         While many of the cells captured in this study are primarily found in a specific  
184 organ within the adult, endothelial cells will be distributed across the whole body.  
185 Endothelial cells (ECs) originate by *de novo* vasculogenesis from at least three sites  
186 within the embryo during E7.0-E8.0: the yolk sac, the allantois, and intra-  
187 embryonically in the aortic primordia<sup>20</sup> (Fig. 4A). All subsequently proliferate by  
188 angiogenesis and converge at the base of the allantois, giving rise to the circulatory  
189 system at around E8.5<sup>20</sup> (Fig. 4A). Unsupervised clustering of the four populations  
190 annotated as ECs (Fig. 1C) revealed substantial substructure, identifying six distinct  
191 sub-clusters (Fig. 4B). Interestingly, some ECs had an underlying allantoic signature  
192 (Fig. 4C, blue cluster) characterised by expression of *Tbx4*, *Hoxa10* and *Hoxa11*<sup>21</sup>.

193         Within the non-allantoic clusters, cells could be clearly distinguished by their  
194 level of maturity. Elevated levels of *Etv2* pointed towards more immature cells<sup>20</sup> in  
195 the purple and pink clusters, while the mature EC markers *Cdh5* and *Pecam1*<sup>22</sup>  
196 showed increased expression in the green subgroup (Fig.4D). Due to the  
197 developmental stage analysed, we consider that many of the non-allantoic mature ECs  
198 may be of yolk sac (YS) origin<sup>22</sup>. Accordingly, we noted a subset of cells with high  
199 levels of *Lyve1*, which has recently been reported as a marker for yolk sac  
200 haemogenic endothelium (HE; Fig.4C)<sup>23</sup>. Furthermore, adjacent to the HE, two other  
201 clusters - yellow and orange - expressed the haematopoietic progenitor markers  
202 *Runx1*, *Spi1* (PU.1) and *Gfi1b*. This transcriptional profile corresponds to the second  
203 wave of haematopoiesis, where definitive erythroid-myeloid progenitors (EMPs)  
204 emerge in the YS by endothelial to haematopoietic transition (EHT)<sup>24</sup>. Although these  
205 haemogenic cells still expressed an endothelial signature (*Cdh5* and *Pecam1*), the

206 orange cluster displayed lower levels of these markers, indicating their more mature  
207 blood phenotype. This latter group also expressed erythroid (*Gata1*, *Nfe2l3*) and  
208 megakaryocytic (*Fli1*) markers, supporting this notion (Fig.4C).

209         Next we analysed in more detail the transcriptomes of the HE and EMP cells.  
210 Interestingly, we found that *Alox5* and *Alox5ap* were upregulated in these cells,  
211 compared to the rest of the ECs (Fig. 5A), a finding also recapitulated in single  
212 endothelial cells sorted based on *Flkl1* expression<sup>25</sup> (Supplementary Fig. 4A). The  
213 *Alox5* enzyme and its cofactor *Alox5ap* occupy a central position in the production of  
214 leukotrienes from arachidonic acid (Fig. 5B). Thus, we hypothesised that this pathway  
215 might be important in early blood development. To further investigate this, we used  
216 mouse embryonic stem cell (ESC) differentiation assays that recapitulate the  
217 formation of HE and EMP cells *in vitro*.

218         Mouse ESCs were differentiated into embryoid bodies (EBs) and exposed to  
219 the *Alox5* inhibitor Zileuton or to leukotriene C<sub>4</sub> (LTC<sub>4</sub>), between days three to four of  
220 differentiation. EBs were then dissociated, the compounds washed out, and the  
221 number of haematopoietic progenitor cells assessed using colony forming assays (Fig.  
222 5C). While addition of Zileuton caused a dose-dependent reduction in colony  
223 numbers, LTC<sub>4</sub> resulted in a reciprocal increase of up to 3-fold (Fig. 5D). This  
224 demonstrates that the leukotriene pathway plays a previously unrecognised role in  
225 modulating the formation of early blood progenitor cells.

226         Recent advances in single cell expression profiling technology are having a  
227 major impact across almost all areas of biomedical research. In contrast to previous  
228 studies, which have been restricted to small and well-defined populations of cells, we  
229 performed an unbiased sampling of cells from the entire embryo and thus generated a

230 rich resource for the developmental biology community across all major mammalian  
231 organ systems.

232 The identification of subtle sub-structure within the endothelial and  
233 endodermal cell populations suggests that other clusters also contain cryptic and small  
234 subgroups of cells. One key challenge moving forward will be to identify and  
235 characterise these populations in an automated way. This will be particularly critical  
236 for small and rare sub-populations, where discriminating between genuine biological  
237 signal and technical noise will be challenging. Primordial germ cells (PGCs) represent  
238 a well-characterised yet exceedingly rare cell population in the developing embryo<sup>26</sup>.  
239 Our processing pipeline did not identify a separate cell cluster for PGCs; however,  
240 targeted interrogation of the dataset revealed 25 cells that expressed high levels of the  
241 very specific PGC marker gene *Stella* (*Dppa3*) along with several other genes  
242 expressed in PGCs<sup>26</sup> (Supplementary Fig. 5A-B and Supplementary Table 4).

243 Additional challenges come from the somewhat philosophical question of how  
244 to define a cell type: here the boundaries can quickly get blurred, especially in  
245 dynamically developing systems where the concept of a continuum of cellular states  
246 may be more appropriate than rigid cell type categorizations. This concept is well  
247 illustrated in the context of somitogenesis, where our data shows a smooth continuum  
248 along the differentiation path from mesodermal progenitors to somitic cells. By  
249 ordering cells in a trajectory, we identified and validated spatially-restricted patterns  
250 of wave-like expression, including additional candidate regulators such as *Cited1*.

251 The endothelial cells from our dataset could be divided both by maturity and  
252 by their location of origin within the embryo. Macrophages are also found across the  
253 entire adult organism, and are thought to acquire tissue-specific molecular signatures  
254 following migration, presumably driven by distinct microenvironmental signals.

255 Interestingly, we observed that endothelial cells could be partitioned into two major  
256 groups based on a gene expression signature specific to allantoic mesoderm. In  
257 contrast to macrophages, endothelium may therefore have a tissue-of-origin signature  
258 from very early in development. It will be fascinating to explore how this initial  
259 patterning may influence the diverse range of endothelial functions.

260 Blood cells develop in close association with other mesodermal tissues, in  
261 particular the endothelium, where flat endothelial cells undergo a profound change in  
262 cell shape to give rise to round blood progenitor cells, through an endothelial to  
263 haematopoietic transition (EHT)<sup>24</sup>. Although EHT has been recognised as a key step  
264 that will require optimization to achieve robust *in vitro* production of blood cells from  
265 pluripotent stem cells<sup>27</sup>, much remains to be learned about the underlying molecular  
266 processes. We identified the haemogenic endothelial cells as well as the blood  
267 progenitors they give rise to; access to the full transcriptomes of these key  
268 developmental populations *in vivo* allowed the subsequent identification of the  
269 leukotriene biosynthesis pathway as a regulator of early blood development.

270 Unlike the previously identified transcriptional regulators of EHT such as  
271 *Runx1* or *Gfi1/Gfi1b*<sup>28</sup>, the leukotriene pathway will be easier to exploit in a  
272 translational setting because of the ready availability of small molecule agonists and  
273 antagonists. Leukotrienes are produced in a multi-step process from arachidonic acid,  
274 which can be metabolised into a number of distinct functionally active molecules, all  
275 with their own receptors and spectrum of biological activities, including the fine-  
276 tuning of haematopoietic stem cell activity at the time of their first emergence in the  
277 aorta-gonad-mesonephros region at E11.5<sup>29</sup>. Of note, the arachidonic acid derivatives  
278 prostaglandin and epoxyeicosatrienoic acid have been identified in small molecule  
279 screens for compounds that can amplify blood stem and progenitor cells<sup>30,31</sup>, and have

280 already entered clinical trials to enhance blood stem cell transplantation<sup>32</sup>. However,  
281 there is as yet no evidence to suggest that prostaglandin or epoxyeicosatrienoic acid  
282 function endogenously during early blood progenitor development. It will be  
283 intriguing to decipher how the leukotriene pathway promotes the formation of blood  
284 progenitor cells, and to incorporate its manipulation into current protocols for *in vitro*  
285 production of blood cells for regenerative medicine and drug development  
286 applications.

287         In summary, our analyses have characterised all major cell populations (both  
288 embryonic and extra-embryonic) present in a post-gastrulation mammalian embryo.  
289 Our results provide a rich resource for the scientific community that can be used for  
290 different purposes. For instance, by combining our reference atlas with data from *in*  
291 *vitro* differentiation protocols it is possible to rigorously assess the ability to  
292 efficiently generate a particular lineage. Additionally, our dataset facilitates both  
293 hypotheses generation and the identification of marker genes to isolate specific  
294 populations for further study. To this end, we have created a tool to browse the  
295 expression of any gene, including those we have identified as potential markers for  
296 specific lineages (<http://marionilab.cruk.cam.ac.uk/organogenesis/>).

401 **Figure Legends:**

402 **Fig. 1: Single-cell RNA-seq of whole mouse E8.25 embryos identifies 20 major**

403 **cell types. A)** E8.25 whole mouse embryos were dissociated and processed with the

404 10X genomics platform to capture single cells and produce libraries for RNA

405 sequencing. A representative image of the sequenced embryos is shown. **B)** Violin

406 plots indicating the number of UMIs and genes obtained per cell. A boxplot is shown

407 on the inside (center line, median; box limits, upper and lower quartiles; whiskers,

408 1.5x interquartile range; n = 19,396 cells). **C)** t-SNE plot of all the cells that passed

409 quality control (19,396) computed from highly variable genes; the first two

410 dimensions are shown. Cells with similar transcriptional profiles were clustered into

411 33 different groups, as indicated by the different colours. Each cluster was annotated

412 based on the expression of marker genes into 20 major different cell types. Several

413 cell types are composed of two or more clusters. PSM = presomitic mesoderm.

414

415 **Fig. 2: Sub-structure within the E8.25 mouse foregut. A)** Diffusion map of the

416 foregut endoderm cells (Fig. 1C; n = 185); the first two diffusion components (DC)

417 are shown. The different colours correspond to three sub-clusters detected by the k-

418 branch algorithm. Based on their expression pattern (see panel B), likely identities of

419 early endoderm cells (red), hepatic progenitors (blue) and thyroid and lung

420 progenitors (yellow) were assigned. **B)** Heatmap showing the average expression of

421 the top 5 most differentially expressed genes in each of the three sub-clusters

422 (indicated by the coloured bars on top) along with well-characterised marker genes.

423 The colour gradient is  $\log_{10}(\text{normalised counts} + 1)$ . **C)** Principal Component

424 Analysis of the foregut, midgut and hindgut cells from the mouse (circles; n = 437)

425 and human pluripotent stem cell derived foregut progenitor cells (diamonds; n = 3);

426 the first two components are shown. The human samples are closest to the mouse  
427 foregut cells.

428

429 **Fig. 3: Oscillating patterns of gene expression during somitogenesis can be**  
430 **inferred from scRNA-seq data.** **A)** Schematic of mouse somitogenesis, which  
431 proceeds along the anteroposterior (AP) axis. From the tail-bud (posterior) extends the  
432 presomitic mesoderm (PSM) which gives rise to somites (anterior). On the right,  
433 travelling waves of gene expression of oscillatory genes are shown along with  
434 signalling gradients on the AP axis; FGF and Wnt are posterior-high while retinoic  
435 acid (RA) has the opposite pattern. **B)** Diffusion map of the cells from the mesoderm  
436 progenitors (MP), presomitic and somitic mesoderm clusters (n = 2999), ordered  
437 based on the expression of genes correlated with *Fgf8* expression; the first two  
438 diffusion components (DC) are shown. The colour gradient indicates the trajectory  
439 from MP to somites as a pseudo-space measurement. **C)** Heatmap of the genes  
440 involved in establishing signalling gradients. *Aldh1a2* is the enzyme that synthesises  
441 RA while *Cyp26a1* degrades RA. Cells have been ordered in pseudo-space on the x-  
442 axis. Each gene is regularised so that expression values are within [0,1]. **D)**  
443 Expression changes along the pseudo-space trajectory can be clustered into six  
444 groups, one of which (last) shows a wave-like pattern consistent with oscillatory  
445 expression. **E)** Heatmap of the expression of all genes in the last cluster from D. Cells  
446 have been ordered in pseudo-space on the x-axis. Each gene is regularised so that  
447 expression values are within [0,1]. **F)** Representative heatmap of the same genes on  
448 the dissected PSM of an embryo that was split into five segments from posterior to  
449 anterior, as schematised at the far right in A. Six biological replicates were analysed,  
450 all with similar results; the other five replicates are presented in Supplementary Fig.

451 3B. **G)** Regularised logistic fit of the expression across the pseudo-space for genes  
452 with well-characterised oscillatory expression<sup>16</sup>. Most show a wave-like pattern. **H)**  
453 Expression pattern of *Cited1* in dissected segments of PSM from most posterior to  
454 most anterior, for six different biological replicates. The gene shows a wave-like  
455 pattern, and different embryos peak at different regions of the PSM.

456

457 **Fig. 4: The endothelium can be subdivided based on maturity and location of**  
458 **origin.** **A)** Schematic diagram of how endothelial cells (ECs) and the circulatory  
459 system are formed in the embryo. **B)** t-SNE plot of the cells in the four endothelial  
460 clusters (n = 871). Left: original clusters coloured as in Fig. 1C. Right: colours  
461 correspond to the redefined subclusters. The first two dimensions are shown. **C)**  
462 Heatmap of the top 5 differentially expressed genes across subclusters, along with  
463 well-characterised genes for the endothelium. Coloured bars indicate the new cluster  
464 (top) and original cluster (bottom) they belong to. Each gene is regularised so that  
465 expression values are within [0,1]. **D)** Expression patterns of the endothelial markers  
466 *Etv2*, *Cdh5* and *Pecam1* on the t-SNE from B. The colour gradient is  $\log_{10}(\text{normalised}$   
467  $\text{counts} + 1)$ . ECs: endothelial cells; EMPs: erythroid-myeloid progenitors.

468

469 **Fig. 5: The leukotriene biosynthesis pathway drives blood formation.** **A)** Heatmap  
470 showing the characteristic genes of erythro-myeloid progenitors (EMPs) and  
471 haemogenic endothelium within the non-allantoic mature endothelial cell (EC) cluster  
472 (Fig. 4C). The colour gradient is  $\log_{10}(\text{normalised counts} + 1)$ . See also  
473 Supplementary Fig. 4A. **B)** Schematic diagram of the leukotriene biosynthesis  
474 pathway, highlighting the functions of ALOX5, ALOX5AP and the position of the  
475 leukotriene C4 (LTC<sub>4</sub>). **C)** Experimental setup for embryonic stem cell (ESC)

476 differentiation to embryoid bodies (EBs) and haematopoietic colony formation assays.  
477 **D)** Bar plot showing the fold change in number of colonies relative to carrier control  
478 when EBs were treated with the indicated concentrations of Zileuton or LTC<sub>4</sub> for 24  
479 hours. Bars represent the mean plus standard deviation of three biological replicates.  
480 The individual data points are shown as open circles. Statistically significant changes  
481 compared to controls were tested with a one-tail Student's t test (p-value = 0.004 for  
482 Zileuton-50μM; 0.002 for Zileuton-100μM; 0.027 for LTC<sub>4</sub>-100μM; 0.007 for LTC<sub>4</sub>-  
483 300μM;).

## 1 **Online Methods**

### 2 **Embryo collection and single-cell RNA sequencing**

3 All mice were bred and maintained at the University of Cambridge, in microisolator cages  
4 with sterile bedding; sterile food and water were provided *ad libitum*. All animals were kept  
5 in specified pathogen-free conditions. All procedures were performed in strict accordance to  
6 the United Kingdom Home Office regulations under project number PPL70/8406. Timed  
7 matings were set up between C57BL/6 mice. Upon dissection, only embryos staged as 4-  
8 somite pair embryos (Theiler Stage 12) according to the morphologic criteria of Downs and  
9 Davies were kept. Suspensions of cells were prepared by incubating the embryos with  
10 TrypLE Express dissociation reagent (Life Technologies) at 37°C for 10 minutes and  
11 quenching with heat inactivated serum.

12 For the first sample, 16 embryos were pooled together whereas a second sample  
13 consisted of 7 independent embryos. The first sample was run in two independent channels of  
14 the Chromium 10X Genomics to generate single-cell libraries for high throughput  
15 sequencing; the second sample was processed in a single channel, at a later date. All samples  
16 were multiplexed together and sequenced across two flow cells of an Illumina HiSeq 2500, to  
17 generate paired-end 100bp data.

18 For the replication experiment, timed matings were set up between C57BL/6 x CBA  
19 F1 mice. Embryos were processed in the same way as above, except in this case single  
20 embryos were used and the extraembryonic ectoderm was removed upon dissection. Each  
21 sample was run in two independent channels of the Chromium 10X Genomics. All samples  
22 were multiplexed together and sequenced across six lanes of an Illumina Hi-Seq 2500.

23

### 24 **Data processing with the Cell Ranger package and quality control**

25 Sequencing data was processed with the Cell Ranger 1.1.0 software to align, filter and count  
26 UMIs per sample. Data was mapped to the mouse reference genome GRCm38.p4 and the  
27 transcriptome annotation from the Ensembl database, version 84  
28 (<http://mar2016.archive.ensembl.org/index.html>). The resulting data comprised 20,819 cells

29 from all three samples. Data from all samples were consolidated into a single dataset using  
30 the *cellranger aggr* program, which downsamples the depth of different samples to make it  
31 equivalent across the whole dataset. We removed all cells that expressed less than a thousand  
32 genes or that had more than 3% of their transcripts mapped to mitochondrial genes. We  
33 further removed any cells that expressed both *Xist* and any of *Kdm5d*, *Eif2s3y*, *Gm29650*, *Uty*  
34 or *Ddx3y* (genes in the Y chromosome) as these are likely to be doublets. We identified 400  
35 cells that could be affected by index swapping (since they share the same cell barcode with  
36 another cell), even though the rates of this phenomenon are very low for the HiSeq 2500.  
37 However, these were scattered across the whole tSNE and there was no difference in their  
38 library size or number of genes expressed. Therefore, these cells were not removed.

39

#### 40 **Data normalisation**

41 The data were normalised for cell-specific biases using the method proposed in Lun et al.  
42 (2016)<sup>33</sup> and implemented in the Bioconductor package *scrn*<sup>34</sup>. To calculate size factors,  
43 genes with mean expression lower than 0.1 were filtered out; the *quickCluster* function was  
44 used to obtain the initial clustering of the cells (method *igraph*). The estimated size factors  
45 were used to normalise all genes expressed in at least one cell. Normalised counts are  
46 provided with the ArrayExpress submission.

47

#### 48 **Identification of highly variable genes and dimensionality reduction**

49 For downstream analyses we filtered out all genes with mean expression lower than 0.01. To  
50 identify highly variable genes, we implemented the distance-to-median (DM) method  
51 proposed in Kolodziejczyk et al. (2015)<sup>35</sup>, and called as highly variable those with the 20%  
52 highest DM values. We discarded all genes from the Y chromosome, *Xist*, haemoglobins and  
53 ribosomal protein genes. Spearman's correlation coefficient was computed from this set of  
54 genes and then used to build a distance matrix defined as  $\sqrt{((1-\rho)/2)}$ . A t-SNE plot was  
55 constructed from the distance matrix, using the *Rtsne* package<sup>36</sup>.

56

## 57 **Clustering of cells into distinct populations**

58 To classify cells into different clusters we used hierarchical clustering on the distance matrix  
59 (see above; `hclust` function in R, with *average* method) followed by the dynamic hybrid cut  
60 algorithm (*dynamicTreeCut* package<sup>37</sup>) to define clusters (*cutreeDynamic* function in R with  
61 the *hybrid* method and a minimum cluster size of 60 cells). Cells that were outliers and could  
62 not be assigned to any cluster by the algorithm were removed. This resulted in the definition  
63 of 20 clusters.

64 We further searched for substructure in each of these clusters. For each cluster, we  
65 defined the set of highly variable genes and computed the distance matrix as detailed above.  
66 We then used hierarchical clustering and the dynamic hybrid cut algorithm (minimum cluster  
67 size of 40 cells) to define clusters. In cases where more than one cluster were identified, we  
68 performed a stability analysis by subsampling the number of cells and genes to 2/3 of the total  
69 and identifying clusters with the same procedure; we then used the Jaccard coefficient to  
70 assess the similarity of the obtained clusters with the full and subsampled data. This  
71 procedure was repeated a hundred times and clusters with a median Jaccard index of at least  
72 0.5 were split. This resulted in 33 clusters that could not be stably subdivided further.

73 To annotate each cluster we examined the expression of well-characterised marker  
74 genes. Several groups of clusters that were adjacent in the t-SNE plot were all annotated as  
75 the same cell type; whereas they differ in the expression of subsets of genes, they share the  
76 core of gene markers that characterise them as a single population. We annotated 20 distinct  
77 cell types. We tested whether the proportions of cells from each sample were different for  
78 each of these 20 subpopulations with a Pearson's chi-squared test (p-values corrected for  
79 multiple testing using the Benjamini & Hochberg method; Supplementary Table 1). Only five  
80 were significantly different, three of which were the extraembryonic subpopulations; this is  
81 consistent with extraembryonic tissues being more susceptible to biased recovery upon  
82 dissection of the embryos.

83

## 84 **Identification of germ layer marker genes**

85 To identify genes that had specific expression in particular populations of cells, we used  
86 *edgeR*<sup>38</sup> to perform differential expression analysis. For this, we used *scran*'s function  
87 *convertTo* to create a DGElist object with the data and the appropriate size factors for  
88 normalisation. We then defined the groups to test by classifying each cluster from Fig. 1C  
89 into endoderm, mesoderm or ectoderm (as indicated in Supplementary Fig. 1E). Finally, we  
90 used generalised linear models to test each pairwise comparison (through *glmFit* and *glmLRT*)  
91 and corrected the returned p-values for multiple testing using the Benjamini & Hochberg  
92 method.

93 To identify genes that are preferentially expressed in a given germ layer, we first  
94 computed the third quartile for each gene across the 20 cell populations (Fig. 1C). We  
95 excluded all genes with a value greater than zero in more than 10 populations; this ensures  
96 that the genes to be analysed are not ubiquitously expressed. For each germ layer, we required  
97 significant adjusted p-values (FDR < 5%) in their comparisons against the other two germ  
98 layers, and a positive log-fold-change, to retain the genes significantly upregulated. The  
99 resulting gene lists can be found in Supplementary Table 2.

100

### 101 **Characterisation of early specification of foregut cells**

102 To characterise the substructure within the foregut cells, we recomputed the set of highly  
103 variable genes as described above, and selected those that were highly correlated among  
104 them. We then constructed a diffusion map on the log-transformed matrix of expression of  
105 these genes in the foregut cells (*DiffusionMap* function with default options, *destiny* R  
106 package<sup>39</sup>). To find sub-clusters, we used the k-branches algorithm<sup>40</sup> on the first two diffusion  
107 components (*kbranches.global* function in *kbranches* R package; the parameter *fixed\_centre*  
108 was set to the averages of DC1 and DC2). The gap statistics (performed with *clusGap*  
109 function in *cluster* package<sup>41</sup>) suggested the existence of three sub-clusters (Supplementary  
110 Fig. 2A). We identified differentially expressed genes between these three sub-clusters in an  
111 analogous way as described above for the germ layers. The resulting gene lists can be found  
112 in Supplementary Table 3.

113

#### 114 **Induction of human pluripotent stem cells into foregut progenitors**

115 Human embryonic stem cells were differentiated towards foregut using chemically defined  
116 media as described in<sup>42</sup>, and harvested at day 7 of differentiation. Three biological replicate  
117 samples were analysed by bulk RNA-seq using standard Illumina protocols. Reads were  
118 mapped to Ensembl GRCh38, release 77 (<http://oct2014.archive.ensembl.org/index.html>), of  
119 the human genome using TopHat 2.0.10<sup>43</sup>. We supplied TopHat with the gene model  
120 annotations and known transcripts using the option '-GTF'; all other parameters were left  
121 with their default values. Only read alignments with mapping quality score MAPQ>10 were  
122 kept for further processing. Finally, we used *featureCounts*<sup>44</sup> from the Subread package to  
123 count the number of reads mapping uniquely to exons.

124

#### 125 **Comparison of induced human foregut progenitors to the mouse cell atlas**

126 First, we recomputed the highly variable genes for the foregut and mid-hindgut  
127 subpopulations and computed the distance matrix as described earlier. We found three  
128 clusters using a dynamic tree cut algorithm (minimum cluster size of 30); based on the  
129 expression of marker genes we annotated these as foregut, midgut and hindgut.

130 We then ran the “pairs” classifier<sup>15</sup> implemented in the *scraper*<sup>34</sup> R package to compare  
131 the human foregut stem cell samples to the mouse endodermal cells from the fore-, mid- and  
132 hindgut clusters (Supplementary Fig. 2B). The classifier was trained on the mouse data with  
133 the *sandbag* function, by considering only genes with a 1:1 human ortholog (as annotated in  
134 the Ensembl database) that were differentially expressed between the three clusters of mouse  
135 gut cells.

136 For the Principal Component Analysis shown in Fig. 2C we used the top 200 genes  
137 that were differentially expressed between the three clusters of mouse gut cells, further  
138 restricted to 1:1 orthologs in human. In order to reduce confounding effects due to technical  
139 reasons, quantile normalisation was performed jointly on the mouse and human data.

140

### 141 **Pseudo-space ordering of presomitic and somitic cells**

142 The mesoderm progenitors, presomitic and somitic mesoderm cells are split into four clusters.  
143 We noted that the smallest cluster of presomitic mesoderm (light green in Fig. 1C) is scattered  
144 across the tSNE and, also, that these cells have a significantly higher number of genes  
145 expressed compared to the rest of the dataset; this might indicate the presence of doublets.  
146 Thus we excluded this cluster from downstream analyses. To order the remaining cells along  
147 the anteroposterior (AP) embryo axis, we reasoned we could use the information provided by  
148 the *Fgf8* signalling gradient, which decreases as cells become more anterior. When visualised  
149 in a tSNE plot, the three remaining clusters showed a trajectory correlated to *Fgf8* expression  
150 levels. However, there was a group of cells negative for *Fgf8* at the start of the trajectory that  
151 instead expressed markers of the adjacent neural tube cluster. We thus identified the  
152 substructure in the mesoderm progenitors cluster and removed the subpopulation of cells that  
153 did not express *Fgf8*.

154 To order cells along the *Fgf8* gradient, we first identified the top 300 genes  
155 significantly correlated (both positively and negatively) with *Fgf8* using the *correlatePairs*  
156 function from *scran*<sup>34</sup>. We visually inspected this set of genes and removed any that did not  
157 increase or decrease monotonically, retaining 260 genes. We then used the expression data of  
158 these genes to construct a diffusion map (*DiffusionMap* function in the *destiny* package<sup>39</sup>).  
159 Finally, we calculated the diffusion pseudotime with the *DPT* function to order the cells along  
160 the inferred trajectory. We refer to this quantity as pseudo-space, since the cells were ordered  
161 along the embryo's AP axis.

162

### 163 **Identifying genes that have dynamic expression along pseudo-space**

164 To identify genes that change their expression levels along the pseudo-space trajectory we  
165 regressed the binarised expression levels (1=expressed; 0=not expressed) along the pseudo-  
166 space of all genes with mean expression of at least 0.1. For this we fitted a constant or a  
167 degree 2 model using local logistic regression (*locfit* function, with *nm* set to 1 and binomial  
168 as the *family*) and calculated Akaike's information criterion (AIC) for each. We selected

169 genes that were better fitted by the degree 2 model by computing the difference ( $\Delta$ AIC) of  
170 the AIC of the degree 2 model minus the AIC of the null model. We retained all genes with a  
171  $\Delta$ AIC < -25.

172 To cluster the genes into different patterns of expression we predicted, for each gene,  
173 the values of the degree 2 model fit along the pseudo-space axis, and standardised each to be  
174 contained within [0,1]. We then computed Spearman's correlation matrix and transformed it  
175 into a dissimilarity matrix by using the transformation  $\sqrt{((1-\rho)/2)}$ . Finally, we used  
176 hierarchical clustering (method *average*) on the distance of the dissimilarity matrix, followed  
177 by the dynamic hybrid cut algorithm<sup>37</sup> (minimum cluster size of 80) to define groups.

178

### 179 **Validation of dynamic expression along the presomitic mesoderm**

180 To confirm that the genes we identified as possible oscillating genes in the PSM were indeed  
181 cycling, we collected additional C57BL/6 embryos to isolate the PSM. Upon dissection, only  
182 pre-turned embryos were kept. Embryos were dissected in M2 media. The mesoderm was  
183 separated from the other germ layers after treatment with pancreatin for one minute at 37°C.  
184 The left and right sides of the PSM were finely dissected using tungsten needles, and each  
185 was cut into five segments along the anteroposterior axis. Each segment was collected in 15 $\mu$ l  
186 of lysis buffer (0.2% Triton X100 plus 1:20 RNase inhibitor (Clonetechn)) that had been  
187 prepared fresh at the start of the dissections. Samples were vortexed, centrifuged and frozen  
188 on dry ice.

189 To prepare libraries for RNA-seq, samples were first processed with the Smart-seq2  
190 protocol as described previously<sup>45</sup>; libraries were prepared using the Illumina Nextera XT  
191 DNA preparation kit. All libraries were pooled and sequenced on the Illumina HiSeq 4000  
192 platform.

193 Data were aligned to the same mouse genome and annotation as used for the single  
194 cell data, with STAR 2.5.2a<sup>46</sup>. The numbers of fragments mapped to each gene were counted  
195 with the program *featureCounts*<sup>44</sup> from the Subread package. Samples with fewer than three

196 million reads were discarded. The remaining data was normalised for differences in depth of  
197 sequencing by using the method implemented in DESeq2<sup>47</sup>. To model the expression pattern  
198 across the AP axis (segments 1 -> 5), we fitted a degree 2 model using local linear regression  
199 (*locfit* function, with *nn* set to 1); then we used this model to predict the expression levels  
200 across 17 regularly spaced intervals from most posterior to most anterior, to generate  
201 smoother profiles (Fig. 3H and Supplementary Fig. 3C).

202

### 203 **Characterisation of molecular signatures within endothelial cells**

204 For the endothelium study, we selected all cells in the four clusters annotated as endothelium  
205 (Fig. 1C). First, we re-calculated the highly variable genes and computed the distance matrix  
206 and tSNE as described above. We used hierarchical clustering (method *average*) followed by  
207 the dynamic hybrid cut algorithm<sup>37</sup> (minimum cluster size of 20) to define groups. To  
208 characterise each subcluster, we used the *findMarkers* function from *scrna*<sup>34</sup> to identify genes  
209 that were preferentially expressed in a given group of cells; we removed genes with a median  
210 expression above zero in all subclusters. For the heatmap in Fig. 4C, we selected the top 5  
211 differentially expressed genes for each cluster plus other informative markers based on the  
212 literature. We used these to annotate each cluster's identity.

213

### 214 **Assessing the role of the leukotriene pathway on blood production**

215 HM-1 murine embryonic stem (ES) cells (kindly provided by David Melton) were grown in  
216 Knock-Out DMEM (Gibco) supplemented with 15% serum batch tested for maintenance of  
217 pluripotency (Hyclone), 1000 U/ml leukaemia inhibitory factor (LIF) (Millipore), 2 mM  
218 L-glutamine/100 U/ml penicillin/100 µg/ml streptomycin (Gibco), 0.1 mM β-mercaptoethanol  
219 (Gibco) at 37°C, 5% CO<sub>2</sub>, on gelatinised plates (Falcon, Corning) at a plating density of  
220 ~2×10<sup>4</sup> cells/cm<sup>2</sup>. Pluripotency was validated by their ability to differentiate into derivatives  
221 of the three germ layers. Cells were split every 2-3 days as necessary. ES cells were validated  
222 by their ability to differentiate into derivatives of the three germ layers and tested negative for  
223 mycoplasma contamination.

224 ES cells were harvested and plated on gelatinised dishes at a density of  $4 \times 10^4$   
225 cells/cm<sup>2</sup> in standard ES growth medium (described above). 24 hours later the cells were  
226 dissociated and plated on gelatinised dishes at a density of  $4 \times 10^4$  cells/cm<sup>2</sup>. 24 hours later the  
227 cells were dissociated again and washed once with PBS to remove all remaining ES medium  
228 and LIF. The cells were resuspended in IMDM based *in vitro* differentiation (IVD) medium  
229 containing 15% serum batch tested for EB differentiation (Gibco), 10% protein free  
230 hybridoma medium II (Gibco), 2 mM L-glutamine/100 U/ml penicillin/100 µg/ml  
231 streptomycin, 0.15 mM MTG, 180 µg/ml human transferrin (Roche) and 50 µg/ml L-ascorbic  
232 acid (Sigma) at a density of  $10^4$  cells/ml. The cells were plated in Costar low adherence 6-  
233 well plates (Corning) and incubated for 4 days at 37°C / 5% CO<sub>2</sub> to form EBs. Zileuton  
234 (Sigma), LTC<sub>4</sub> (abcam) or carrier were added on day 3 at the indicated concentrations (Fig.  
235 5D). The EB suspension was harvested on day 4, transferred to appropriate tubes and the EBs  
236 were left to settle by gravity for 10 minutes. The medium was discarded, the EBs were  
237 washed with PBS and left to settle again by gravity. PBS was removed and the EBs were  
238 completely dissociated by addition of 1 ml TrypLE and gentle pipetting. TrypLE was  
239 inactivated by adding 10 ml IMDM containing 20% EB serum. The cells were counted,  
240 centrifuged at 300×g for 5 minutes at room temperature and resuspended in IVD medium.  
241  $4 \times 10^4$  cells were transferred in 4 ml of Methocult GF M3434 (Stem cell technologies)  
242 supplemented with 100 U/ml penicillin / 100 µg/ml streptomycin (Gibco). 1 ml aliquots were  
243 plated in triplicate in 35 mm low adherence dishes (Corning). Colonies were counted on  
244 day 14 and differences in colony numbers were tested with a two-tailed Student's t-test.

245 To ensure that treatment with Zileuton or LTC<sub>4</sub> does not affect the proliferation of the  
246 mESCs,  $10^6$  cells were harvested by centrifugation after dissociation of EBs on day 4 and  
247 washed in PBS. The cell pellet was resuspended in residual volume and fixed by dropwise  
248 addition of ice cold 70% methanol. The cells were incubated at 4°C for 1 hour and then  
249 washed twice with PBS. The cells were resuspended in 300µl of propidium iodide (PI)  
250 staining buffer (200µg/ml RNaseA, 20µg/ml propidium iodide, 0.1% Triton X100 in PBS)

251 and stained at room temperature for 1 hour. The cells were analysed on a BD Fortessa. Post-  
252 acquisition analysis was performed with the FlowLogic suite (Supplementary Fig. 4B-C).

253 To ensure that treatment with Zileuton or LTC<sub>4</sub> does not affect the viability of the  
254 mESCs, 10<sup>6</sup> cells were harvested by centrifugation after dissociation of EBs on day 4 and  
255 washed in PBS. The cells were resuspended in 100µl Annexin binding buffer (10 mM  
256 HEPES, 150 mM NaCl, 5 mM KCl, 1 mM MgCl<sub>2</sub>, 1.8 mM CaCl<sub>2</sub>) containing 5µl Annexin V  
257 APC (BD Biosciences; Cat. no. 550474; Lot. 16808) and 1 µg/ml DAPI. The cells were  
258 diluted up to 400 µl with Annexin binding buffer and analysed on a BD Fortessa cytometer.  
259 Post-acquisition analysis was performed with the FlowLogic suite (Supplementary Fig. 4D).

260

#### 261 **Code availability**

262 The R code used is available on request.

263

#### 264 **Data availability**

265 The processed data reported in this paper have been tabulated and are available together with  
266 the raw data in ArrayExpress under accession numbers E-MTAB-6153 for the C57BL/6  
267 dataset; E-MTAB-5728 for the C56BL/6 x CBA dataset; and E-MTAB-6155 for the  
268 validation of oscillating genes in the presomitic mesoderm dataset. All other data supporting  
269 the findings of this study are available from the corresponding author on reasonable request.
