Technique project 4 - Duodeno e pancreas separati_Aug_11MB.mp4
Background:

Ideal surgical treatment for acute duodenal injuries should guarantee a definitive treatment, with reasonably low morbidity and mortality, but also simple and easily reproducible by acute care surgeons in emergency setting. Duodenal injury due to major perforated or bleeding peptic ulcers or iatrogenic/traumatic perforation, represents a surgical challenge, with high morbidity and mortality. Our aim was to review management of these injuries and assess the outcomes of a definitive surgery with a pancreas-sparing ampulla-preserving duodenectomy.

Methods:

Pancreas-sparing ampulla-preserving D1-D2 duodenectomy was used for patients presenting with major duodenal injuries over a 5-years interval (March 2012-November 2017). The ampulla was identified and preserved by using a transcystic/transpapillary tube. The outcomes were recorded.

Results:

Ten patients were treated with this technique: seven with perforated or bleeding peptic ulcers, two iatrogenic perforations and one with blunt abdominal trauma. Mean age was 78 years (range 65-84). Four patients were haemodynamically unstable. The location of the duodenal injuries was always D1 and/or D2, above or in close proximity to the ampulla of Vater. The surgical approach was open in nine patients and laparoscopic in one. The mean duration of surgery was 264 min (range 170-377'), all patients were post-operatively transferred to ICU (mean ICU stay 4.4 days, range 1-11), and overall mean hospital stay was 17.8 days (range 10-32). Six patients developed major postoperative complications: cardiorespiratory failure in 5 patients, gastrointestinal complications in another 4. Surgical re-operation was needed in one patient for postoperative necrotizing and bleeding pancreatitis. No leaks from duodenal stump, gastro-jejunal anastomosis or bile duct strictures were observed. 30-days mortality rate was 20%.

Conclusions:

Pancreas-sparing ampulla-preserving D1–D2 duodenectomy for emergency treatment of 'major' duodenal perforations is feasible and associated with satisfactory outcomes.
Definitive surgical management of major duodenal (D1 – D2) perforations.

TWEET: The difficult duodenum, KEEP IT SIMPLE! How to do a “Pancreas-sparing & ampulla-preserving duodenectomy @BJS @salo75
**INTRODUCTION AND BACKGROUND**

Urgent surgery for duodenal perforation is a major challenge for surgeons. This is due to the intrinsic difficulty of repairing large duodenal perforations with major loss of tissue by simple surgical measures (e.g. primary repair, omental patch). Alternatively, diverting/excluding procedures (pyloric exclusion, proximal gastric disconnection, serosal or jejunal patch etc) often result in poor outcomes and high rates of persistent duodenal fistula. The disappointing results achieved by conservative and simple surgical strategies can be overcome by definitive, major resection such as pancreaticoduodenectomy, however, this requires advanced hepatobiliary expertise and carries risks associated with technical complexity. Arguably the most definitive outcome would be achieved by formal duodenal resection, including the large perforation and area of duodenum. This type of duodenectomy could be quick and technically straightforward, and easily reproducible by surgeons of varying skill levels. The pancreas the ampulla of Vater and common bile duct should be preserved, thus avoiding the morbidity and mortality associated with emergency Whipple's procedure. There are a number of causes of major duodenal perforation including perforated peptic ulcer or bleeding duodenal ulcer, traumatic perforation (blunt or penetrating), and iatrogenic/endoscopic perforations (SDC1–SDC2). Also duodenal leak after initial conservative management or of primary repair can be a cause. The size of a perforation is the most relevant prognostic factor influencing the choice of surgical treatment, but there is controversy in what constitutes major or giant duodenal perforation. The traditional definition of giant duodenal ulcer is size greater than 2 cm; these are associated with much higher morbidity and mortality. Gupta et al proposed that duodenal perforation can be classified into three main groups (1) small perforation (less than 1 cm in size); (2) large perforation (between 1 cm and 3 cm); (3) giant perforation (exceeding 3 cm in size). Aim of this study is to review the current management of the major duodenal injuries and to identify which major duodenal injuries are not safely manageable by primary repair alone and/or other non-resectional surgical strategies, requiring a definitive resection of the diseased duodenum and therefore classify the indications for a duodenectomy (Tab 1-SDC). Further aim is to describe in an educational step-by-step fashion a safe and reproducible technique for performing a D1-D2 pancreas-sparing and ampulla-preserving duodenectomy (Video 1); Fig. 1 illustrates what type of “major” duodenal perforation is the ideal candidate for such definitive D1-D2 duodenectomy and analyse the clinical outcomes in our series of patients treated with this technique.

**METHODS**
Ten patients (7 M/3 F) were treated by a single Consultant surgeon over a 5 year interval, between March 2012 and November 2017 (Tab. 2-SDC). The mean age of the patients was 78 years (range 65-84). Preoperative haemodynamic shock was present in four patients and ASA scores ranged from III-E to V-E. Seven patients had perforated or bleeding peptic ulcers, two had iatrogenic perforations (one post lap chole and the other after endoscopic duodenal stent insertion), and one patient had blunt abdominal trauma. The location of the injuries was always D1 and/or D2, above or close to the ampulla of Vater on the anti-mesenteric border.

**Surgical technique** (Video 2): The procedure can be performed either open or laparoscopically, depending on the patient's hemodynamic status, aetiology and location of the perforation, skills and experience of the operating surgeon. Initial assessment includes identification and localization of the exact site of the duodenal injury. In the case of bleeding duodenal ulcer, duodenotomy may be required for locating the exact site of the ulcer and assessing if the bleeding can be effectively controlled with a simple overrun or if definitive management and a duodenal resection are needed. In case of giant perforated ulcers or iatrogenic perforations, especially if the lesion is posterior or retroperitoneal, identification and localization may be difficult and opening the retroperitoneum for evacuation of large periduodenal collections may be necessary. This manoeuvre can be challenging and potentially dangerous since the planes of dissection are adherent to the extraluminal collection, increasing the risks of duodenal tears or of enlarging the defect. Incision of the peritoneal reflection and entering the collection with careful blunt dissection and medial mobilization of the entire C-shaped duodenum, is the key (Step 1a-1b). Second step is performing the cholecystectomy and identifying the cystic duct by cannulation with a trans-cystic drain (Step 2). The trans-cystic tube is pushed into the CBD, progressed through the papilla into the duodenal lumen to identify precisely the location of the ampulla and its anatomical correlation to the site of the duodenal perforation. This allows a thorough assessment of the feasibility of a proximal duodenectomy with preservation of the ampulla. The transcystic tube is then retrieved allowing to precisely assess whether the staple line on the supra-ampullary duodenum is falling on healthy tissues and if the whole perforation and devitalised margins are entirely comprised within the resected duodenal tract. After carefully locating the ampulla, the next step is to disconnect the gastric antrum and pylorus from the gastric body. The duodenal resection should start proximal to the pylorus, where less inflamed. Gastrocolic ligament is opened. The lesser sac is entered and the posterior wall of the gastric antrum is mobilized. This step continues with division of the lesser omentum.
Pyloric vessels are ligated, the antrum and pylorus are mobilized and gastric distal resection can be performed with a linear stapler (Step 3). Disconnecting the gastric antrum allows one to flip over the specimen and permits easier dissection of the posterior aspect of the antrum and D1 from the head of the pancreas. The next step is proceeding downwards with dissection of the first part of the duodenum and the superior duodenal flexure from the head of the pancreas (Step 4). This step is facilitated by having already disconnected the antrum, which can flipped over to stay on a correct disecting plane between the duodenal wall and pancreatic parenchyma. The small vessels connecting the medial duodenal wall to the head of the pancreas can be safely controlled with bipolar forceps, haemoclips or fine ties. Following this plane, the pancreatic head can be spared and preserved, whilst the duodenum is detached. The division of the second part of duodenum from pancreatic head is continued downwards, below the superior duodenal flexure, staying on a plane between the duodenal wall and the upper and lateral border of pancreatic head, until reaching the level of insertion of the ampulla onto the medial side of duodenum (Step 5). The trans-cystic tube is left trans-papillary, to mark for a safe, ampulla-preserving, resection. This also helps avoid iatrogenic injury to the ampulla and/or CBD and avoid accidental detachment of the ampulla from the medial wall of the duodenum during separation of the supra-ampullary duodenum from the pancreatic head. The next step is to place an articulating stapler tangentially across healthy margins of the mid-duodenum, just above the ampulla. Use of a flexible endo-stapler makes this step easier, because endostaplers can be articulated and angled to reach a sharp oblique orientation (Step 6). In fact, the perforation site is usually located on the lateral side of the duodenal wall. Such oblique stapling can achieve a nearly-total resection of D2 with complete closure and full stapling of the remaining distal duodenum, over healthy margins and, at the same time, avoid injuries to the orifice of the ampulla within the lumen of the medial duodenal wall (SDC3). We recommend that the trans-cystic tube is retracted back into the CBD, before stapling across the duodenum, to prevent its entrapment (Step 7). After stapling and completion of the D1-D2 resection, a good tight seal of the entire duodenal staple line can be verified with a leak test using methylene blue injected from trans-cystic or T-Tube drain (SDC4). Trans-cystic drain is then left at the level of distal CBD for the purpose of external bile diversion. In selected cases, biliary external diversion can be achieved more effectively by a T-tube in the CBD. Finally, GI continuity is restored by a Roux-en-Y gastrojejunostomy (Step 8). Postoperative imaging of the remaining duodenum can be obtained via trans-cystic cholangiogram or CT cholangiography to rule out leaks from the duodenal stapled stump and/or the patency of the CBD and ampulla (SDC5).
RESULTS

Nine patients underwent open surgery, either via midline laparotomy or rooftop incision; one who was haemodynamically stable was treated laparoscopically. In all patients, a D1 or a D1 + D2 duodenectomy was performed. Cholecystectomy and transcystic T-tube insertion for identification of the location of the ampulla and for postoperative biliary external diversion was used in all patients except the laparoscopic one. GI tract continuity was restored by Roux-en-Y reconstruction in 8 cases. Major associated surgical procedures were spleno-pancreasectomy of the body-tail in one case due to 10 cm neuroendocrine gastrin-secreting carcinoma of the pancreatic body. Median operative time was 241 minutes (mean 264 min, range 170-377). N-J tube for postoperative enteral feeding was added in 6 cases. Mean postoperative ICU stay was 4.4 days (median 3.5 days, range 1-11). Overall mean duration of postoperative hospital stay was 17.8 days (median 16.5 days, range 10-32). Postoperative morbidity was common and occurred in nine patients; six major, three minor. Complications included cardiorespiratory (major in 2, minor in 3) which required critical care. Four patients developed gastrointestinal complications including a bleeding from the gastrojejunal anastomosis managed by endoscopic haemostasis; a postoperative necrotizing and bleeding pancreatitis requiring multiple re-laparotomies; a peripancreatic stump collection managed by percutaneous CT-guided drainage and finally a biliary leak around the T-tube insertion in a patient who had surgery for iatrogenic perforation after endoscopic placement of a palliative biliary-duodenal stent (SDC1-2-3). There were no leaks from the peri-ampullary stapled duodenal stump or strictures of the common bile duct. Two patients died, one for severe necrotizing pancreatitis and the other for cardiorespiratory failure (30-days mortality 20%). Final histology of the duodenal resected specimen was in all cases free of malignancy.

DISCUSSION

Major perforated and/or bleeding duodenal ulcers as well as duodenal traumatic injuries are not common, and their management can be technically demanding. Postoperative morbidity and mortality rates are extremely high, especially when a postoperative leak occurs after initial attempt of primary repair. Choosing rapid and easily reproducible techniques such as simple closure with omental patch (Cellan Jones or Graham) or a derivative antrectomy with reconstruction but without definitive resection of the affected tract of the duodenum, often have disappointing outcomes in patients having major duodenal ulcer perforation and poor preoperative general conditions. Re-operation for gastric disconnection due to postoperative leakage and bleeding has been often reported in such cases. Despite its high morbidity and consequences on quality of
life, gastric disconnection was recommended with the aim of bailing out definitive surgery and deferring restoration of GI continuity to a later stage. Lal in 2009 reported a 70% rate of postoperative leakage after primary repair of 20 cases with perforation >2cm, with 8 patients (40%) requiring re-exploration and more invasive delayed procedures such as duodenal exclusion, partial gastrectomy, jejunal serosal patch or jejunal pedicled graft, free omental plug, gastric disconnection and triple tube ostomy. The intrinsic problem with all these strategies is that the diseased duodenum is not addressed by definitive surgical treatment in a timely fashion. Ultimately, this delay in obtaining a definitive source control by duodenal resection resulted in high mortality rates, reaching 65% in the group of patients with large and giant perforation who underwent initial primary closure with Cellan-Jones or Graham omental patch. Other authors reported a lower postoperative mortality rate with simple closure and vagotomy than with simple closure alone (12.5% vs 26.7%) and lower recurrence rate (38.1% vs 63.6%)\textsuperscript{9}. Nonetheless five years postoperatively, the cumulative recurrence rate after simple closure (41.2%) was significantly higher than that after resection (15.9%) and the authors recommend gastric resection. The choice of procedure must be tailored to the nature of the defect, the amount of tissue lost and amount of peritoneal contamination\textsuperscript{10}. Risk and consequences of a leak are exacerbated by the high intraluminal pressures, extrusion of duodenal mucosa through the closure and autodigestion by pancreatic enzymes and bile. Therefore, an adjunctive external biliary diversion should be strongly considered. There is increasing agreement that when facing a “giant” perforated ulcer (>2 cm), both the Graham patch and primary closure of the ulcer are less successful and a more definitive operation (eg, vagotomy with pyloroplasty or partial gastrectomy) is usually recommended\textsuperscript{11}. Particularly challenging cases may occur especially when a retroperitoneal abscess is found, as these are associated with posterior perforation of a duodenal ulcer. In such cases kocherization of the duodenum, visualization of the ulcer and primary repair of the ulcer can be difficult to achieve. Therefore, partial duodenectomy with a duodenal-jejunal anastomosis was described with successful outcome\textsuperscript{12}. Some authors have attempted a pancreas-sparing complete duodenectomy but detachment and re-implantation of the duodenal ampulla represents a significant technical challenge, resulting in higher postoperative leakage and complication rates\textsuperscript{13}. A pancreas-sparing partial or subtotal/total duodenectomy with translocation of ampulla and distal CDB has been described for certain types of benign duodenal tumors\textsuperscript{14}, premalignant or early malignant duodenal lesions\textsuperscript{15} or infra-ampullary lesions including selected malignancies\textsuperscript{16, 17}. Elective pancreas-sparing duodenectomy has also been described as an emergency procedure for duodenal trauma, major bleeding
peptic ulcers or duodenal diffuse ischemia with 20% mortality and no GI-related postoperative complications. Paluszkiewicz et al. reported five cases with complex and extensive duodenal injuries. Two patients required resection of the entire duodenum (D1 to D4) while three had the distal duodenum (D2 to D4) resected. The reconstruction described here is technically challenging and time-consuming, requiring an anastomosis between isolated ampulla or surrounding mucosal patch to the side of a jejunal loop, leading to increased risk of leakage, pancreatitis and pancreatic fistula. For duodenal trauma, Ivatury suggested that most duodenal penetrating injuries may be treated effectively by primary repair. Pyloric exclusion has been advocated for complex traumatic injuries, but associated with longer hospital stay and ultimately no survival or outcome benefits compared to primary repair only. Complex duodenal injuries, those diagnosed and treated late, and those associated with major destruction of adjacent structures require careful consideration of the physiologic stability of the patient, severity of injury, extent of local inflammation and experience of the surgeon. Recent studies suggested that a decrease in the use of damage control laparotomy in trauma is associated with decreased use of resources, without increasing morbidity and mortality. The present technique may represent an easily reproducible surgical strategy for definitive management of moderate-severe grade duodenal traumatic injuries, which cannot be satisfactorily managed with simple repair or exclusion/derivative techniques and not necessarily requiring an emergent trauma-Whipple’s. This technique also has the advantage of being easily reproducible by most surgeons, although tube duodenostomy and damage control might be safer in small centers and in absence of hepatobiliary expertise.
ACKNOWLEDGMENTS
The authors acknowledge the contribution of Mr. Sherman Kwan in reviewing the final draft of the manuscript for its content and English style and of Mrs Clarissa Ann Elisabeth Gelmi, medical student intern in Surgery, in collecting the patient’s data. Finally the authors would like to acknowledge a special Mention to my colleague Mr Justin Davies, Clinical Director for Digestive Diseases at Addenbrooke’s Hospital, Cambridge University Hospitals NHS Trust, for critically revising the manuscript and helping to make the final round of revisions after peer review.
