Visible-Light-Driven CO₂ Reduction by Mesoporous Carbon Nitride Modified with Polymeric Cobalt Phthalocyanine

Souvik Roy and Erwin Reisner*

Abstract: The integration of molecular catalysts with low-cost, solid light absorbers presents a promising strategy to construct catalysts for the generation of solar fuels. Here, we report a photocatalyst for CO₂ reduction that consists of a polymeric cobalt phthalocyanine catalyst (CoPPc) coupled with mesoporous carbon nitride (mpg-CNₓ) as the photosensitizer. This precious-metal-free hybrid catalyst selectively converts CO₂ to CO in organic solvents under UV/Vis light (AM 1.5G, 100 mW cm⁻², λ > 300 nm) with a cobalt-based turnover number of 90 for CO after 60 h. Notably, the photocatalyst retains 60% CO evolution activity under visible light irradiation (λ > 400 nm) and displays moderate water tolerance. The in situ polymerization of the phthalocyanine allows control of catalyst loading and is key for achieving photocatalytic CO₂ conversion.

Photocatalytic reduction of CO₂ to produce storable fuels offers an attractive path to capture and utilize the greenhouse gas CO₂ and ultimately implement a carbon-neutral energy cycle. The development of efficient, sustainable, and economically viable catalysts and light-absorbers lies at the nexus of solar-fuel research on CO₂ utilization. Hybrid photosynthetic systems with molecular catalysts immobilized on solid supports (light-absorbing semiconductors or dye-sensitized semiconductors) have recently emerged as a promising approach for suspension-based photoreactor applications, because they combine the selectivity of molecules with the durability of heterogeneous materials.[1] While many earth-abundant metal based molecular complexes have been reported for CO₂ reduction in homogeneous solution, there are relatively few examples of heterogenization of these catalysts on solid light-absorbers.[2] The development of new robust catalyst–photosensitizer interfaces remains a challenge that offers the key for improved photocatalytic activity of colloidal material–molecule hybrid systems.

Graphitic carbon nitride (g-CNₓ) has recently emerged as a promising semiconductor for photocatalytic applications,[3] including water splitting[4] and CO₂ reduction,[5] because of its nontoxicity, facile synthesis, capability to absorb UV as well as visible light, and durability under photochemical conditions. A relatively narrow band gap and sufficiently negative conduction band energy minimum (~1.10 V vs. NHE at pH 6.6)[4b,6] allow g-CNₓ to harvest UV/Vis light and subsequently reduce a surface-bound molecular catalyst via photoinduced electron transfer. In CNₓ-based photocatalytic systems for CO₂ reduction, different types of co-catalysts have been used, including weakly anchoring phosphonic acid functionalized Ru complexes or Ru-Re dyads,[6,7] molecular cobalt and iron complexes in solution,[8] metalloporphyrins covalently grafted on CNₓ,[9] single-atom cobalt sites incorporated in the material,[10] and sodium niobite nanowires.[11] Despite encouraging reports with CNₓ–porphyrin hybrid catalysts,[9,12] a CNₓ/molecular catalyst system that consists of only earth-abundant elements and is entirely heterogeneous, durable, efficient, and selective for CO production remains an elusive target. Cobalt phthalocyanine is a known electrocatalyst for CO₂ reduction,[13] but has rarely been explored in photocatalysis.[14]

Herein, we report photocatalytic reduction of CO₂ to CO by a robust organic–inorganic hybrid material in which mesoporous carbon nitride (mpg-CNₓ) harvests solar energy and activates a surface-deposited polymeric cobalt phthalocyanine (CoPPc; Pp denotes polymeric phthalocyanine) catalyst toward CO₂ reduction (Figure 1). CoPPc is deposited on mpg-CNₓ via an in situ polymerization method, which represents an effective strategy for catalyst immobilization.

Figure 1. Schematic illustration of light-driven CO₂ reduction catalyzed by mpg-CNₓ|CoPPc hybrid (potentials reported against NHE; VB and CB denote valence and conduction band, respectively).
This study demonstrates that the polymer–CNx interface plays a key role in catalysis by enabling the transfer of photoexcited electrons from CNx to the attached CoPPc catalyst.

Mpg-CNx was prepared by heating cyanamide in air using colloidal silica as a hard template, which was subsequently solidified (Figure S1). Formation of the polymeric catalyst was observed by a color change from pale orange to green. A weak π-π stacking interaction between the polymeric phthalocyanine sheet and tri-s-triazine units of mpg-CNx may contribute toward the facile charge transport through the interface. The cobalt content in the hybrids (mpg-CNxCoPPc; \( a = \mu \text{mol Co g}^{-1} \)) was modulated by controlling the amount of TCNB during the synthesis. Catalyst loadings, determined by inductively coupled plasma optical emission spectrometry (ICP-OES), were in the range of 4.1–107 \( \mu \text{mol Co g}^{-1} \) with higher Co content causing a visible intensification of green color of the solid (Figure S1).

Successful formation of CoPPc on mpg-CNx was confirmed by diffuse reflectance UV/Vis spectroscopy (DRS), attenuated total reflectance infrared (ATR-IR), Raman, and X-ray photoelectron spectroscopy (XPS). DRS of mpg-CNxCoPPc shows the characteristic \( (S \rightarrow S_1) \) Q band of CoPPc at 700 nm, which is red-shifted compared to the monomeric cobalt phthalocyanine (CoPc) (670 nm in DMF), consistent with its polymeric structure (Figure 2A). Figure 2B shows that the Raman spectrum of mpg-CNx is featureless, whereas that of the hybrid materials displays bands originating from CoPPc. The ATR-IR spectrum of mpg-CNxCoPPc is dominated by mpg-CNx peaks, which mask the weaker CoPPc stretches (Figure S2).

The introduction of CoPPc leads to a lower Brunauer–Emmett–Teller (BET) surface area of the hybrid material (104 m\(^2\) g\(^{-1}\) for mpg-CNxCoPPc vs. 134 m\(^2\) g\(^{-1}\) for bare mpg-CNx, Figure S3), suggesting that the catalyst deposition occurs not only on the surface, but also inside the mesoporous structure. However, the integration of CoPPc does not affect the periodic stacking of the lamellar structure of CNx, as demonstrated by powder X-ray diffraction (Figure S4). XPS spectra of pure CoPPc polymer and mpg-CNxCoPPc at different catalyst loadings are shown in Figure 2C and Figure S5. The Co 2p region of all samples consists of peaks at 796.2 and 780.8 eV associated with Co2p\(_{3/2}\) and Co2p\(_{1/2}\) transitions, respectively. The satellite features at \( \approx 802 \) and \( \approx 786 \) eV, which are characteristic of Co\( ^{2+} \) paramagnetic species, are clearly discernible for CoPPc and mpg-CNxCoPPc but are less pronounced for lower cobalt contents. The C 1s XPS spectra of mpg-CNxCoPPc feature a more intense peak at 284.8 eV, which can be attributed to the C(sp\(^2\))–C(sp\(^2\)) bonds of CoPPc (Figure S6). The intensity of this peak increases with higher catalyst loading.

Transmission electron microscopy (TEM, Figure 2D, S7), scanning electron microscopy (SEM, Figure S8) and energy-dispersive X-ray (EDX) analysis (Figures S7–S9) of mpg-CNxCoPPc confirm a uniform distribution of Co throughout the material (particle size ca. 200–500 nm from SEM). TEM images of the hybrid reveal CoPPc material as a network, interwoven with CNx, domain (Figure 2D and Figure S7).

The overpotential required for CO\(_2\) reduction by CoPPc was estimated by cyclic voltammetric analysis of CoPPc/carbon nanotube (CNT) composite electrodes. The cyclic voltammogram of CoPPc/CNT in a mixture of acetonitrile (MeCN) and triethanolamine (TEOA) (4:1 v/v) displays a large catalytic wave under CO\(_2\) with an onset at \( \approx -0.91 \) V vs. NHE (Figure S11), which suggests that CO\(_2\) reduction by CoPPc occurs at a more positive potential compared to the conduction band of CNx.

The photocatalytic activity of the mpg-CNxCoPPc hybrid was studied in CO\(_2\)-saturated MeCN under UV-filtered simulated solar light irradiation (100 mWCm\(^{-2}\), AM 1.5G, \( \lambda > 400 \) nm) with TEOA as a sacrificial electron donor. While bare mpg-CNx generates only trace amounts of \( \text{H}_2 \) and CO (headspace analysis by gas chromatography), the CoPPc-modified material (mpg-CNxCoPPc) exhibits considerably higher activity toward CO\(_2\) reduction to CO (red trace, Figure 3A). Mechanically mixed pure CoPPc and mpg-CNx is inactive toward CO\(_2\) reduction (blue trace, Figure 3A), highlighting the importance of the in situ polymerization. Only trace amounts of formate (\( < 1 \mu \text{mol g}^{-1} \)) were detected in all systems by ion chromatography.

This hypothesis is further supported by the low CO evolution activity of a suspension of mpg-CNx with monomeric CoPc in solution (green trace). CO was not observed in control experiments without mpg-CNx, TEOA, CO\(_2\), or light.
Isotope labeling studies with $^{13}$CO$_2$ using mass spectrometry and infrared spectroscopy confirmed that CO was produced from CO$_2$ (Figures S12 and S13). Irradiation of mpg-CN$_x$|CoPPc under visible light equipped with a long-pass filter ($>455$ nm) produced very little CO, which is consistent with mpg-CN$_x$ as the light absorber. To confirm that the cobalt phthalocyanine units in the polymer are the active catalyst and not single-site cobalt ions coordinated to the tri-s-triazine moieties of CN$_x$[10], mpg-CN$_x$|CoCl$_2$ was synthesized by heating CoCl$_2$ and mpg-CN$_x$ in the absence of TCNB under identical reaction conditions (weight ratio 1:120; equivalent to CoCl$_2$ used for mpg-CN$_x$|CoPPc$_{107}$ synthesis). This material displays minimal activity toward CO$_2$ reduction (purple trace). A non-mesoporous carbon-nitride-based hybrid (g-CN$_x$|CoPPc) is also inactive under identical condition (orange trace).

The hybrid catalysts change color from pale green to purple during photocatalysis, indicating photoreduction of the Co centers of CoPPc (Figure 3B, inset). UV/Vis absorption spectra of an acetonitrile suspension (20% TEOA, v/v) of Co centers of CoPPc (Figure 3B, inset). UV/Vis absorption spectra of a mpg-CN$_x$|CoPPc$_{107}$ suspension in MeCN/TEOA (0.11 mg ml$^{-1}$) before and after illumination ($>400$ nm, 5 min) under CO$_2$. Photographs of the suspension before and after illumination are shown in the inset.

Photocatalytic activity of mpg-CN$_x$|CoPPc is largely dependent on the catalyst loading as illustrated in Figure 4A. The amount of CO generated increased linearly with cobalt loading until $\approx 12$ $\mu$mol Co g$^{-1}$. Further increase in cobalt content ($>20$ $\mu$mol g$^{-1}$) resulted in a decrease in activity and only a trace amount of CO was detected for the highest loading sample (107 $\mu$mol Co g$^{-1}$). At high cobalt concentrations, the carbon nitride surface is completely sheathed by the CoPPc layer, which blocks the incoming light and reduces the accessibility of the mpg-CN$_x$ surface to TEOA, thereby hindering photocatalysis. The amount of CO evolved vs. Co loading profile fits well with the selectivity toward CO exhibited by mpg-CN$_x$|CoPPc (Figure 4A, Table S2). Long-term photocatalysis experiments show that the catalyst remains active for 4 days and only displays a marginal decrease of CO selectivity, highlighting the stability and robustness of the photocatalyst assembly (Table S2 and Figure S16).

Under full solar spectrum irradiation ($>300$ nm), mpg-CN$_x$|CoPPc$_{107}$ generated 1000 $\mu$mol CO g$^{-1}$ after 48 h with 85% selectivity (TON$_{CO} = 54$), which corresponds to a 65% increase in activity compared to that under visible light alone (607 $\mu$mol CO g$^{-1}$ after 48 h, TON$_{CO} = 51$) (Figure 4B, Figure S17, and Table S3). Similarly, mpg-CN$_x$|CoPPc$_{107}$ exhibited a 45% increase in activity under UV/Vis irradiation and a small improvement in selectivity toward CO. This observa-
tion is consistent with the high UV absorbance (<400 nm) of mpg-CN. However, this enhancement becomes less pronounced at higher Co loading as demonstrated by the similar TONCo values observed for mpg-CN | CoPPc21.7 under visible and UV/Vis irradiation (Figure 4B, red traces). The external quantum efficiency (EQE) for CO formation by mpg-CN | CoPPc21.9 was calculated to be 0.11% and 0.03% at λex = 360 and 400 nm, respectively (see Table S4 and Figure S18 for more information).

The amount of CO evolved in three 12 h recycling tests displays excellent agreement with that produced during continuous irradiation under visible light, consistent with heterogenous catalysis (Figure 4C). When the runtime for each cycle was shortened to 4 h, the catalyst displayed a significant induction period and the CO evolution peaked during the 5th cycle with subsequent gradual loss of activity. The use of a larger amount of catalyst is likely responsible for the delay as light scattering in concentrated suspension becomes a limiting factor. However, the catalyst retains its excellent selectivity up to the 11th cycle (44 h). In a long-term experiment, the catalyst was recycled after 26 h visible light photocatalysis and it retained 84% activity in the second run for 38 h (Figure S19).

Monitoring the cobalt content of the mpg-CN | CoPPc21.4 under visible light photocatalysis reveals ≈20% loss of cobalt over the initial 4 h (Figure S20). However, very little Co subsequently leached from the photocatalyst between 4 and 48 h. XPS analysis of the catalyst after 24 h photocatalysis confirms that Co remains on the mpg-CN surface (Figure S21).

Addition of water to the reaction medium affects the performance of the photocatalyst. In comparison to the photocatalytic experiments in which CO is produced by mpg-CN | CoPPc21.7 under visible light in MeCN, the activity drops to 41% and 26% in the presence of 10% and 20% water, respectively (Figures S22 and 23). The reduced activity in water is likely caused by the phase separation of MeCN/H2O/TEOA mixture during photocatalysis, with mpg-CN | CoPPc being partitioned into the bottom aqueous layer (Figure S22C).[22] When dimethylacetamide (DMA) was used as the solvent,[23] the reaction mixture remained monophasic and the photocatalyst exhibited markedly improved water tolerance (Figures S24 and 25). Compared to the experiments in DMA, mpg-CN | CoPPc11.9 retains 90% and 78% CO evolution activity in the presence of 10% and 20% water, respectively. Under fully aqueous conditions, the photocatalyst produced 62 μmol CO g−1, corresponding to ≈5.1 turnovers per Co. Water-tolerance is an important feature as it may enable the photoreduction of CO2 using water as an electron donor.

Previously reported CNx-based photocatalysts for CO2 reduction commonly employed either molecular co-catalysts that remained in the solution phase or phosphonic acid functionalized Ru complexes and Ru/Re dyads that interact weakly with the CNx via its surface -NH2 groups.[7b,8a,23] Only a few examples of hybrid materials with immobilized molecular catalysts have been reported, including a Coporphyrin covalently attached to CNx,[23] and a mechanically mixed Fe-porphyrin/CNx hybrid.[23] In the former case, the TONCo and selectivity were reported to be <1 and ≈80% under 80 kPa CO2, respectively, whereas in the latter case, high CO selectivity (98%) was observed with a TON of 5.7. In comparison, the mpg-CN | CoPPc system described here performs well over longer time periods with 90 turnovers after 60 h and displays moderate tolerance toward water. However, this rate is still significantly slower than photocatalytic CO evolution rates displayed by CoPPc | CNT composite electrodes (TON 11240, 24 h electrolysis),[13b] suggesting that photocatalysis is likely limited by the rate of transfer of electron from mpg-CN, to the catalyst and not the inherent CO2 reduction capability of CoPPc. This is supported by the linear decrease of photocatalytic activity of mpg-CN | CoPPc with light intensity, while the selectivity remained unaffected (Figure S26). Notably, the mesoporosity of CNx plays a key role in catalysis by facilitating electron–hole separation through shortening of the migration distance.[25]

In summary, we have interfaced 2D cobalt phthalocyanine sheets with mesoporous carbon nitride via an in situ polymerization technique to fabricate a hybrid catalyst for use in selective CO2 reduction under visible light irradiation. Photocatalysis and spectroscopic studies demonstrate that molecular cobalt phthalocyanine units act as the catalytic centers and that the catalysis is enabled by the immobilization of the polymer in the porous carbon nitride. This work provides a rare example of an effective and robust heterogeneous CO2 reduction photocatalyst featuring inexpensive, earth-abundant components, and provides a versatile platform for catalyst immobilization on heterogeneous light absorbers.
