Abstract

Both the physical and transition-related impacts of climate change pose substantial macroeconomic risks. Yet, markets still lack credible estimates of how climate change will affect debt sustainability, sovereign creditworthiness, and the public finances of major economies. We present a taxonomy for tracing the physical and transition impacts of climate change through to impacts on sovereign risk. We then apply the taxonomy to the UK's potential transition to net zero. Meeting internationally agreed climate targets will require an unprecedented structural transformation of the global economy over the next two or three decades. The changing landscape of risks warrants new risk management and hedging strategies to contain climate risk and minimise the impact of asset stranding and asset devaluation. Yet, conditional on action being taken early, the opportunities from managing a net zero transition would substantially outweigh the costs.

Abstract

Both the physical and transition-related impacts of climate change pose substantial macroeconomic risks. Yet, markets still lack credible estimates of how climate change will affect debt sustainability, sovereign creditworthiness, and the public finances of major economies. We present a taxonomy for tracing the physical and transition impacts of climate change through to impacts on sovereign risk. We then apply the taxonomy to the UK's potential transition to net zero. Meeting internationally agreed climate targets will require an unprecedented structural transformation of the global economy over the next two or three decades. The changing landscape of risks warrants new risk management and hedging strategies to contain climate risk and minimise the impact of asset stranding and asset devaluation. Yet, conditional on action being taken early, the opportunities from managing a net zero transition would substantially outweigh the costs.

Keywords: Sovereign debt, climate change, net zero, transition risk, productivity.

1. Introduction

Advancements in recent decades in climate science and economic modelling, juxtaposed against the real-time observation of the dire consequences of extreme weather events, have revealed important lessons about the macroeconomic consequences of climate change. These are understood to varying degrees. The best understood lessons include: that both the contributions to and consequences of climate change are unequally distributed, that estimates of the economic costs of climate change and corresponding uncertainty, tend to grow, rather than fall over time, that well-designed carbon pricing mechanisms can effectively reduce emissions and inequality, that poorly designed ones do not, and that it is exceedingly difficult to aggregate from the wealth of climate microeconomic studies to make inferences about macroeconomic outcomes.

Among the less understood lessons are the observation that climate investments are cheaper than the alternative – namely, climate-driven disasters. The effects of climate change are severe even in wealthy countries (Kahn et al. 2019), and the consequences of climate change are landing sooner than early models predicted. Many of the biggest risks may fall in the realm of social and political stability rather than extreme weather, and the financial system is far behind and poorly equipped to measure and manage these risks. Recent evidence also shows that many low-carbon and climate resilient investments – from energy and transport infrastructure to buildings and agriculture – are cheaper than their fossil fuel based counterparts, leading to the potential stranding of the carbon-intensive legacy assets they replace (OBR 2021).

Here, we shed light on the comparatively under-researched question of how climate change might affect the financial system and in particular, fiscal sustainability and sovereign debt markets. First, we provide a taxonomy of how the physical and transition impacts from climate change translate into fiscal risks. Second, we review a small but increasingly urgent literature on how these fiscal risks affect sovereign creditworthiness and the cost of public borrowing, with direct implications for fiscal sustainability. Finally, we demonstrate the taxonomy's usefulness using two case studies – one sovereign (the UK) and one industry (renewable energy). Combined, the case studies elucidate two potential uses for our taxonomy, (i) identifying economically relevant blind spots in climate risk analyses and (ii) for understanding feedback mechanisms that must be considered in any attempt to estimate both the costs of decarbonisation and the pace at which it can be achieved. We conclude by reflecting on the types of metrics that could improve the economic assessment of climate risks and how they relate to fiscal decision making.

Our decision to focus on sovereign debt – even in the midst of a zeal for metrics relating to environmental, social, and governance (ESG) investing – is deliberate. Sovereign debt, which is expected to top USD 92 trillion this year (IIF 2021) is by far the world's largest asset class. It is the safe haven to which investors flee in times of turmoil, and its sustainability is what determines the capacity of nations to weather shocks, from Covid-19 to climate change.

Whilst climate-economic models have described in ever greater detail the potential costs of the physical impacts of climate change, we highlight the importance of understanding the *transition impacts* and how they affect *fiscal sustainability*. Our contribution to this special issue is timely, not just with respect to COP26 in Glasgow, Scotland, but also in the midst of unprecedented fiscal disruption in response to the Covid-19 pandemic. Concern over debt-rollover, fiscal space, and the ability to respond to future shocks are now paramount in policy circles. These discussions must include an understanding of how climate change – and our responses to it – will affect the public finances and sovereign debt markets. The topics discussed here are of interest to policy makers and investors concerned with financial system stability, institutional investors and pension managers, and the flow of accurate information through markets – a necessary condition for the efficient management of risk.

2. A taxonomy for translating physical and transition risk into sovereign risk

Although much of the scientific and media attention is understandably focused on extreme weather events, sea level rise, and ecosystem collapse, there are several transmission channels through which climate change can affect public finances and sovereign risks (see, for instance, Figure 1 and Volz et al. 2020). It is now increasingly recognised that the fiscal consequences of climate change and the policy responses to it are not limited merely to the direct physical damages.¹ Indeed, some of the most significant *near-term* impacts on the global economy and public finances, especially in advanced economies, will derive from the climate transition as much as the physical risks from climate change itself. The ‘transition’ reflects the process of decarbonisation, for example the policies, consumer preferences, litigious actions, and technological development that accompany the drive to reduce emissions. Chief among these may be an accelerated pace of human capital obsolescence (and the social disruption this would inevitably bring) as a labour force adapted to the fossil fuel economy struggles to find productive roles in a low carbon world. As a result, it is important to consider the potential risks and opportunities associated with the structural transformation of the economy.

Figure 1. Climate change to sovereign risk: a review of impact pathways

Source: Adapted from Volz et al (2020).

2.1 Depletion of natural capital and ecosystem services

Climate change is expected to have dramatic and adverse effects on natural capital (IPBES 2019). Traditionally, integrated assessment models (IAMs) such as DICE have modelled climate as an independent feature of nature, ignoring feedback loops with the rest of natural capital (such as biodiversity). In contrast, Bastien-Olvera and Moore (2020) construct a GreenDICE model to simultaneously model these linkages, showing that they have long-lasting implications for human welfare, carbon prices, and the optimum investment strategy for addressing climate change. They find that the macroeconomic consequences of emissions are even greater when climate-induced natural capital loss is included and because early investments in biodiversity and ecosystems can partially offset the costs of climate change, they are important components of any climate strategy (Agarwala and Coyle 2020). The nexus of climate and natural capital has several impacts on sovereign risk,

¹ This section builds on Volz et al (2020).

especially for countries in which agriculture, forestry, and fisheries are key industries. But it also impacts the frequency, intensity, and resilience to extreme weather events such as storm surges, fires, floods, and extreme temperatures. The key point is that climate change affects the productive capital stock, output, supply chains, and resilience both directly, but also indirectly through its interaction with other components of natural capital. The associated impacts on the public finances and sovereign risk must be accounted.

2.2 Fiscal impacts of climate-related disasters

Public finances and debt sustainability face exposure to different fiscal risks related to climate disasters (Koetsier 2017). These include both macroeconomic risks and contingent liabilities. Macroeconomic risks related to natural disasters and extreme weather include risks of a disruption of economic activity, which may adversely affect tax income and other public revenues and increase social transfer payments (e.g. Schuler et al. 2019); changes to commodity prices that could affect revenue or increase spending via fossil fuel or food subsidies; effects on inflation and interest rates through supply or demand shocks; and exchange rate effects (e.g. Farhi and Gabaix 2016). Contingent liabilities can explicitly or implicitly expose governments to fiscal risks (Mitchell et al. 2014; Hochrainer-Stigler 2018; Schuler et al. 2019). Natural disasters may damage or destroy physical government assets and public infrastructure, requiring significant expenditure on relief programmes, damage repair, or reconstruction. Indeed, in the US alone, there have been 298 climate-related disaster events with damages in excess of USD 1 billion since 1980, with a total cost of 1.975 trillion in 2021 USD dollars (NOAA 2021).

Natural disasters may also affect the assets or operations of state-owned enterprises. Disasters may damage or destroy private property and require government support for households and corporations to rebuild homes and businesses. To the extent that disasters cause instability to the financial sector, they may force governments to bail out ailing financial institutions. Moreover, disasters can cause a severe humanitarian crisis, which may require public emergency measures, including rescue missions, temporary relocation of people, provision of food and shelter, or medical treatment. Such crisis response measures can be very expensive and have a significant impact on public spending.² Moreover, economic shocks from extreme weather events, although short term in nature, can also have lasting impacts on growth (Acevedo 2014; Klomp and Valckx 2014; Botzen et al. 2019) and public finances.

2.3 Fiscal consequences of adaptation and mitigation policies.

The public sector will have to finance a considerable share of adaptation and mitigation measures. To achieve the Paris climate goals and limit global warming to manageable levels, large investments are needed in a low-carbon transformation of infrastructure and energy systems. Moreover, economies need to invest in resilience to address vulnerabilities from extreme weather events and the effects of gradual global warming. The Global Commission on the Economy and Climate (2016) estimated that globally, until 2030, it will be necessary to spend around \$90 trillion on infrastructure, including energy, all of which needs to be sustainable and climate resilient. While parts of these investments will have to be financed by the private sector, governments will have to play an important role not only in setting the right incentives through climate policies, but also through direct fiscal spending.

² Bova et al.'s (2019) analysis of contingent liability realizations in a sample of 80 advanced and emerging economies for the period 1990–2014 showed that natural disasters (including geophysical events) are one of the most important sources of contingent liabilities, the realization of which can be a substantial source of fiscal distress.

A related concern is that structural shifts throughout the low-carbon transition can disrupt traditional sources of government revenue. Tax revenues from oil and gas production, as well as fuel duties can be a significant source of government revenue. For instance, in 2018, the UK Treasury received about 61.3% of the price charged for each litre of pump fuel sold to consumers; the averages for the G7 and OECD are 50% and 49%, respectively (OPEC 2019). Losing such revenues due to the phaseout of fossil fuels can add significant pressure to public finances. But for some sovereigns the risk is more acute. Jaffe (2020) points out that by far the largest holders of fossil fuel assets are state-owned enterprises. Whilst private oil majors have already begun to diversify their portfolios, the risk that sovereign holdings of fossil fuel reserves may become stranded assets is even more directly linked to sovereign creditworthiness.

2.4 Climate-driven aggregate supply and demand shocks and impacts on output

Both the physical and transition impacts of climate change can cause aggregate supply and demand shocks, with significant implications for output, employment, and public finances. The supply- and demand-side effects of gradual global warming and transition impacts can cause fundamental and enduring structural changes to the economy (Semieniuk et al. 2021). Such impacts can be anticipated across sectors and industries. Both the supply and demand for particular types and locations of housing, insurance products, agricultural output, transport infrastructure, and even university degrees and training programmes are likely to be affected (Hepburn et al 2020).

Current models vary in their projections of the reduction in national output (GDP) arising from different warming scenarios. Conservative estimates project reductions in global per capita GDP of between 7 and 13%, varying significantly across countries depending on the pace of temperature increases and variability of climate conditions, by 2100 (Kahn et al. 2019), mid-range estimates indicate a 7-14% reduction for a 3.5C warming world (Kalkuhl and Wenz 2020), whilst estimates at the higher range indicate a loss of 21% (Burke et al. 2015). A country's long-term growth potential will inevitably have ramifications for its public finances and debt sustainability. These could be even larger if, as recent research suggests, the volatility of temperature rises with its average (Kahn et al. 2019). Kotz et al (2021) show that independent of the rise in average temperature, an increase in the variability of temperature by one degree results in a five percentage point reduction in regional growth rates, on average.

2.5 Impacts on innovation, competitiveness, and efficiency

Most accounts of the effect of climate policies on innovation take an optimistic tone. From Hicks (1932) to Stern (2007) it is argued for instance that carbon prices will induce innovation in low carbon alternatives. However, this presupposes that carbon prices are sufficient to overcome not only the emissions externality, but also any additional market failures (e.g. asymmetric market power, lobbying influence, path dependencies) that tend to favour the status quo. Moreover, if climate-induced innovation takes the form of more efficient complements for carbon intensive industries, such as a more fuel-efficient internal combustion engine, they could serve to further lock-in carbon intensive infrastructure and production. If in contrast, climate-induced innovation accelerates the adoption substitutes such as electric vehicles, the transition may be faster.

Even if the net effect of climate on innovation is positive, genuine concerns about how this translates into fiscal risk remain. For instance, if climate-driven innovations render human and physical capital obsolete, the employment and subsequent social effects could be severe (see Section 2.9). Assets that were initially expected to be productive for many years may become stranded abruptly. Another concern is the global distribution of innovation and its rewards. Countries which delay investment and transition could miss out on first-mover advantages, learning by doing, and global competitiveness.

Finally, the possibility cannot be ruled out that delayed action means that climate change imposes significant physical losses on national output, unevenly distributed across countries. In such a world, it is reasonable to consider that innovation and competitiveness in the hardest hit countries would suffer significantly.

2.6 Effects of climate change on productivity

The direct and transition effects of climate change on productivity are likely to be negative on net, owing largely to its effects on human, physical, and natural capital. The likely effects of warming, and especially rising temperature volatility, on human health and labour productivity are increasingly well established and their consequences for national output are of first order concern (Day et al. 2019). Despite difficulties in distinguishing between supply and productivity effects, empirical studies and model results generally agree that the effect of climate on labour will vary across sectors (indoor versus outdoor work; see Kahn et al 2019 for a within-country study of the ten sectors in the United States) and countries (it will be more severe in the tropics) (Dasgupta et al. 2021). Estimates indicate that heat stress has already reduced labour capacity by 10% in peak temperature months over recent decades, and could rise to a 20% reduction in labour capacity globally in the hottest months by 2050 (Dunne et al. 2013).

The productivity effects are of course not limited to impacts on human capital. Recent years have seen physical infrastructure forced to operate at reduced capacity due to extreme weather events. Obvious examples for the UK include trains operating at reduced speeds due to high temperatures (which affect metal tracks), airport disruption due to winter storms, and local transport disruptions due to floods. In Texas, winter storm Uri in February 2021 triggered a wave of blackouts as energy infrastructure seized in sub-zero temperatures, leaving more than two-thirds of Texans without power for an average of 42 hours during the week of the storm, and an official death toll³ of 151 (Watson et al. 2021). Both the impairment and stranding of physical infrastructure have consequences for productivity estimates and subsequently, macroeconomic risks.

2.7 Climate risks to financial system stability

Climate change, and policy responses to it, pose a material and systemic risk for the financial sector (NGFS 2019, Bolton et al. 2020, Monasterolo 2020). Using an IAM to estimate the expected 'climate value at risk' (climate VaR) of global financial assets, Dietz et al (2016) show that 1.8% of total global financial assets were at risk of climate change along a business-as-usual emissions path, and because risks are concentrated in the tails, this rises to 16.9% for the 99th percentile of climate VaR. This has direct consequences for pensions and investment funds, especially given their heavy exposure to assets that could become stranded in a disorderly transition to net zero (Battiston et al. 2017).

Such climate-induced financial vulnerabilities can spill over to the public sector and give way to a negative feedback loop between financial sector instability and sovereign risk (Acharya et al. 2014, Angelini et al. 2014, Dell'Araccia et al. 2018, Farhi and Tirole 2018, Gennaioli et al. 2018). A weakening of the sovereign balance sheet due to public debt-funded bailouts of banks can further weaken the credit profile of banks due to their sovereign debt holdings and lead to a "doom loop" (Farhi and Tirole 2018). Governments may also rely on domestic banks as a source of funding during periods of financial crisis, putting additional pressure on them to hold more government bonds and worsening the negative feedback effects between financial sector and sovereign risk.

³ Further analysis based on excess death calculations put the death toll between 426 – 978, with a best estimate of 702 (Aldhous et al. 2021).

2.8 Impacts on international trade and capital flows

Climate change can have substantial impacts on an economy's trade in goods and services and capital flows with the rest of the world, with potentially significant ramifications for countries' balance of payments positions and, ultimately, sovereign risk. Both the physical impacts of climate change and the disruptions resulting from the climate policies that trading partners adopt, technological change, or changes to consumption patterns can affect international trade and financial flows. Historically, balance of payments problems have often been at the root of country risk and led to external debt crises (Bouchet et al. 2018). Protracted current account imbalances tend to cause liquidity problems and, if not resolved, solvency problems. The current account balance is therefore an important indicator of sovereign risk.

2.9 Impacts of climate change on political stability

The economic and social effects of climate change may accentuate the social tensions within a society and fuel political instability. Moreover, climate change leads to large-scale migration movements, which could also lead to political tensions or even inter- and intrastate conflicts. Political instability can undermine the ability or willingness of a government to repay its debt. For instance, Clark (1997) emphasised the potential impact of political events on the probability of sovereign default, while Cuadra and Sapriza (2008) maintained that countries that are politically unstable and more polarised have higher default rates and as a result have to pay a higher default risk premium in international credit markets.

These transmission channels are not independent of each other. Climate impacts can magnify the transmission of risk through multiple channels. The socioeconomic and fiscal effects of climate change are multifaceted and depend on the policies taken or not to mitigate and adapt to these risks. Nor is it guaranteed that all of the impacts through these transmission channels will necessarily be negative, that is, exacerbating risk. Particularly around issues of innovation, competitiveness, and productivity, well-designed climate policies can actually serve to reduce sovereign risk. This is especially likely if mitigation and adaptation policies enhance human, physical, and natural capital (Agarwala et al. 2020). Similarly, a revolution in green finance could help support a just transition characterised by high returns as low carbon investments and technologies begin to out-compete their carbon-intensive counterparts. Climate-proofing public finances hence ought to be a key priority of public policy.

3 Climate risks and sovereign creditworthiness

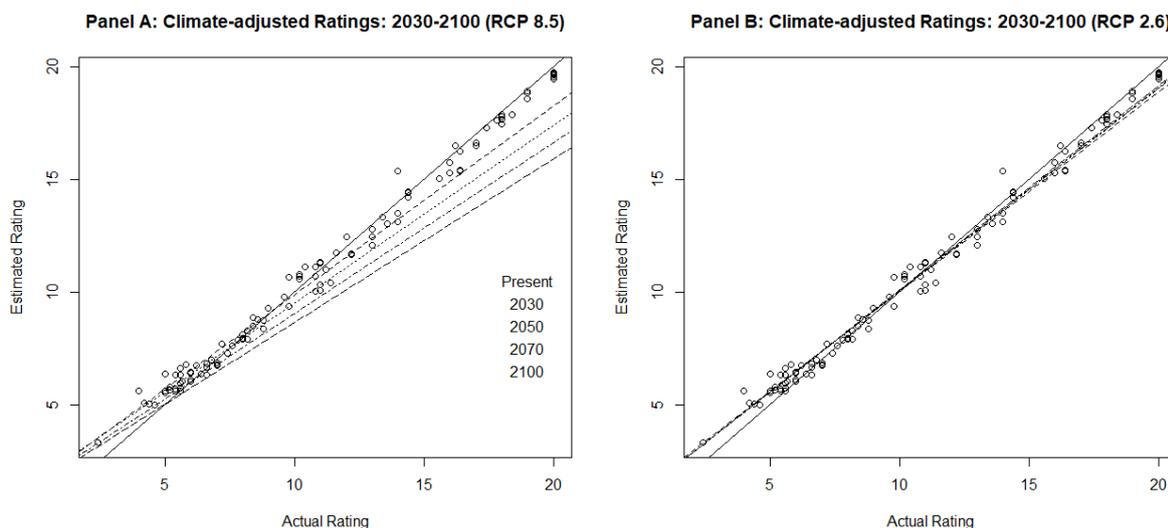

Despite growing evidence of the risk channels outlined in Section 2, mainstream estimates of sovereign risk – especially sovereign credit ratings – have so far been slow to adjust. Although credit ratings agencies (CRAs) have started to discuss climate-related risks, even acquiring climate data firms, there is no statistically significant evidence that sovereign ratings have been affected. This is an important consideration. The efficient market hypothesis depends on the availability of reliable information about risk. If sovereign ratings cannot be shown to respond to the growing scientific and economic evidence of the consequences of climate change, markets and investors may struggle to correctly identify, price, and manage risk throughout their portfolios. Recent empirical analyses suggest that the scientific and economic evidence is sufficient to demonstrate an effect of climate on sovereign creditworthiness.

Cevik and Jalles (2020a) estimate the effect of climate vulnerability on credit ratings of 67 sovereigns between 1995-2017, finding that vulnerability negatively affects sovereign credit ratings. However, this backwards-looking analysis cannot be used to make inferences about the future affect of climate

change on creditworthiness, which is clearly the more important question for managing the public finances over the medium- to long-run.

Klusak et al (2021) is the first paper which offers a forward-look into the effects of climate on sovereign credit ratings. Combining climate-economic models with observed sovereign ratings and an AI model, they construct the world’s first climate adjusted sovereign rating for 108 sovereigns under three climate scenarios. Results indicate that climate change will exert downward pressure on ratings as early as 2030, with an increasing magnitude throughout the century (see Figure 2). Preliminary results show that if global emissions follow their recent trend, the UK could see a 1-notch downgrade (on a 20-notch rating scale) by 2030, growing to more than three notches by the end of century under a high emissions scenario (RCP 8.5). If instead emissions profiles are consistent with limiting warming to 2C, the UK’s sovereign downgrade would be limited to approximately 1-notch by 2100. Zenios (2021) argues that European institutions including the European Commission, European Central Bank, European Stability Mechanism, European Fiscal Board, and member states’ finance ministries should incorporate climate change into sovereign risk assessments.

Figure 2. Climate-adjusted ratings to 2100 (RCP 8.5 versus 2.6)

Source: Klusak et al (2021). The horizontal axis indicates current ratings by S&P and the thick black line represents exact matches between current and predicted ratings. The dotted lines are the best fit lines for climate-adjusted ratings under RCP 8.5 and 2.6, respectively, for 2030, 2050, 2070, and 2100 (Panels A and B).

4 Climate change and the cost of sovereign debt

Weak fiscal positions characterised by high debt, high deficits, and low growth increase sovereign the cost of public borrowing (Barrell and Holland 2009). Whilst early climate models indicated that the worst effect of climate change would accrue far in the future, sovereign debt markets may be expected to price these effects in earlier. Indeed, empirical evidence suggests that climate vulnerability has already raised the average cost of debt in climate-vulnerable developing countries. A first analysis of the nexus between climate vulnerability and the cost of capital by Kling et al (2018) showed that countries with higher exposure to climate vulnerability incur a risk premium on their sovereign debt.⁴

⁴ Kling et al (2021) show that this effect also extends to the corporate cost of capital. Using panel data of 15,265 firms in 71 countries over the period 1999–2017, they invoke panel data regressions and structural equation

Conducting a panel and principal component analysis with annual data for a sample of developing and advanced 46 countries over the period 1996–2016, Kling et al (2018) find that, controlling for macroeconomic factors, climate vulnerability has increased debt costs for a subgroup of 25 climate-vulnerable developing countries by 1.17 percentage points. In absolute terms, this translates into \$40 billion in additional interest payments for 40 climate-vulnerable countries over the period 2007 to 2016 on government debt alone. Projections suggest additional interest payments attributable to climate vulnerability to increase to between \$146 and 168 billion for the same group of countries over the next decade (Buhr et al. 2018).

Subsequent studies have corroborated the positive effect of physical climate vulnerability on the cost of government debt. Using data for 98 advanced and developing countries over the period 1995–2017, Cevik and Jalles (2020) replicate the methodology and measures employed by Kling et al (2018) and confirm their findings. Using refined measures of climate risk and resilience and a higher data frequency for 40 advanced and emerging economies, Beirne et al (2021a) also confirm the findings of a climate risk premium by Kling et al (2018). Moreover, Beirne et al (2021a) develop a set of panel structural VAR models that indicate that the reaction of bond yields to climate risk shocks becomes permanent after around 18 quarters, with high-risk economies experiencing the largest permanent effects on yields. Beirne et al (2021b) conduct an in-depth analysis of the link between climate change and sovereign risk in Southeast Asia, one of the regions most heavily affected by climate change. Both the country-specific and the panel estimates for six Southeast Asian countries with monthly data for the period 2002–2018 show that greater climate vulnerability appears to have a sizable positive effect on sovereign bond yields, while greater resilience to climate change has an offsetting effect, albeit to a lesser extent.

Looking at climate transition risk, Battiston and Monasterolo (2020) employ a financial pricing model with forward-looking simulations to estimate effects of climate risk on the sovereign bond yields of 34 countries. They find that economies that are highly exposed to carbon-intensive sectors incur higher yields on their sovereign bonds. Klusak et al (2021) use an AI-based approach to estimate the additional cost of sovereign and corporate debt resulting from climate-drive downgrades under various warming scenarios. Under the low emissions scenario (RCP2.6) the UK's 0.92-notch downgrade by 2100 would amount to an increase in the annual interest payment on public debt of \$2.0–3.0 billion and an increase of \$250–440 million on corporate debt. Under the high emissions scenario (RCP8.5), this rises to \$7.54–11.31 billion and \$0.94–1.65 billion in additional interest payments on sovereign and corporate debt respectively. These preliminary estimates should be considered severe underestimates because the effect of downgrades is placed on the pre-pandemic level of debt. The figures would grow with the level of debt over the century.

For comparison, figures for G7 plus China show that climate-induced downgrades could increase the cost of sovereign debt by \$18.18–27.27 billion (\$113.93–170.89 billion) under the RCP2.6 (RCP8.5) scenario. The additional annual interest payments of corporations will reach \$5.35–9.36 billion (20.75–36.31 billion) by 2100.

5. Case study: Measuring the impact of a transition to net zero on the UK economy and public finances

In this section we demonstrate how the transmission pathways set out in Section 2 map onto the likely impacts of the UK's transition to net zero on the national economy and the public finances, drawing insights from the UK OBR's recent *Fiscal Risks Report*. The report uses the highly credible UK Climate

models and show that climate vulnerability increases the cost of corporate debt directly and indirectly through its impact on restricting access to finance.

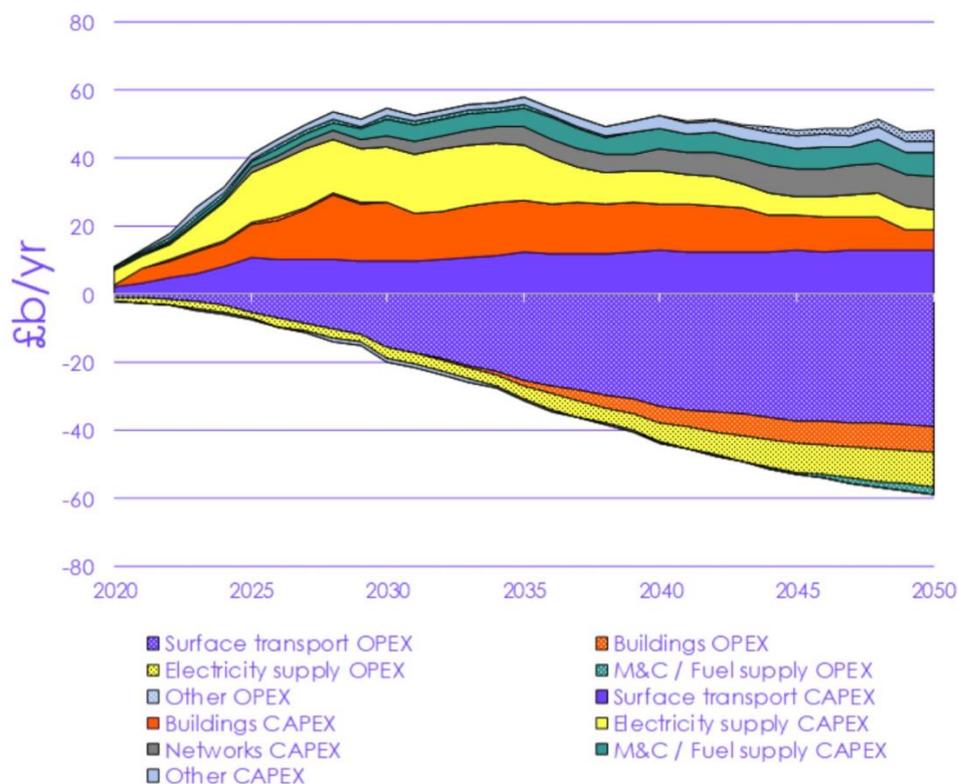

Change Committee (CCC) figures to conclude that meeting net zero will leave GDP 1.4% lower than the hypothetical counterfactual path in 2050 and public debt 21% of GDP higher. This headline analysis needs to be interpreted carefully and masks a much richer story.

Firstly, the likely costs and benefits are unevenly distributed through time. Higher net spending outlays early on are likely to generate higher net revenues down the line, thereby promoting rather than eroding public debt sustainability over the longer term.

Early fiscal outlays must therefore be viewed as investment costs, which expand the public sector's net worth by generating net revenues or public returns down the line. Indeed, the CCC numbers show that by 2050, operating costs in *most* sectors are expected to be lower than under a net zero scenario relative to baseline. Starting with cars, and moving progressively sector by sector, the falls in operating costs become so large that in total they begin to offset the additional capex costs (see Figure 3 below) from around 2040 net 'costs' become negative.

By truncating the cost benefit analysis at 2050, and assessing the integral only over the next 30 years, the OBR analysis includes the bulk of the (front-loaded) investment cost, but excludes decades and centuries of future net gains. The cost savings from eliminating public spending on primary, secondary and tertiary education might also well exceed the loss of revenues from lower wages and social disruption in the first thirty years. But no one would suggest scrapping all education spending would be a sensible long term public policy.

Figure 3. Capital and investment costs and operating cost savings in the Balanced Net Zero Pathway

Source: UK Climate Change Committee (CCC), Sixth Carbon Budget 2021.

The second question surrounds the presumed impact of early action on productivity growth. An accurate prediction of the impact of a low carbon transition on GDP in 30 years' time is, of course, unrealistic. But it is important to note that the numbers quoted by the OBR are not only uncertain, but hugely sensitive to changes in the economy's dynamic productive potential. The OBR's own

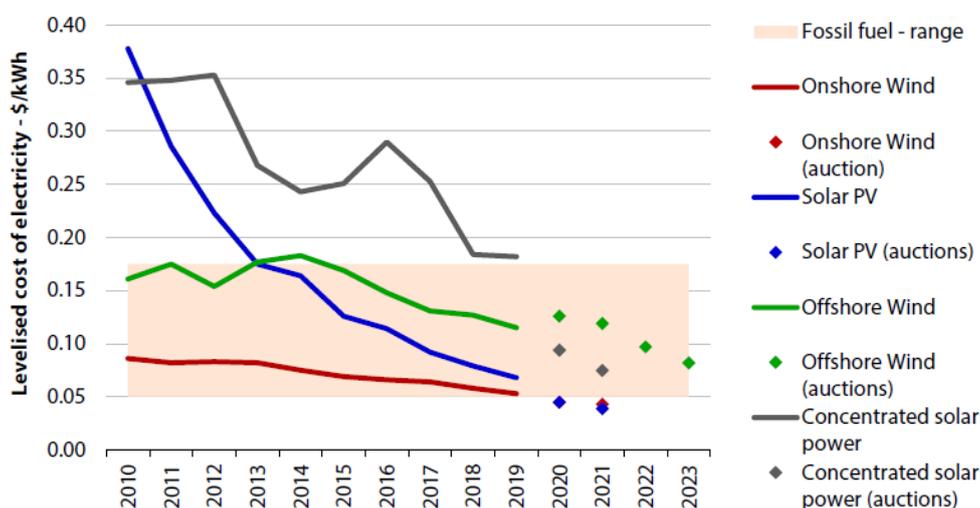

calculations suggest a boost to annual productivity growth of less than 0.05% would potentially wipe this out this loss.⁵

Such a productivity gain is not trivial, were it available. But it is important to recognise that this is not an absolute gain, it is a hypothetical gain assessed against a baseline scenario in which the UK charts a future based on high carbon goods and services. However, such a scenario is highly vulnerable to negative output shocks associated with stranded and devalued assets. There is strong evidence to suggest that investing in cleaner, more efficient, and innovative production is likely to be more productive than relying on the technologies of the previous century. This is even before account is taken of climate damages which can mount much more quickly as productivity growth is eroded through endogenous impact of destroyed or devalued capital (Dietz and Stern 2015).

The economics of innovation and productivity means the cost of meeting various decarbonisation and resource-management targets are not only hard to predict, but that they are path-dependent. Initial conditions and decisions made today, in changing behaviour and generating innovation, matter greatly. Relatively small interventions can generate a virtuous cycle of innovation, investment and falling costs of green technologies as evidenced in the renewable energy and vehicle sectors. By contrast, lock-in of resource- and carbon-intensive infrastructure, behaviour, and institutions increases the cost of attaining sustainable pathways.

The sheer scale of the low-carbon transition generates productivity enhancing network effects and economies of scale in production and discovery. These are already apparent having caught most commentators by surprise. The price of solar photovoltaic (PV) has dropped by 83% since 2010, a period over which the price of wind turbines fell nearly 40% (Liebreich 2018). These technologies are increasingly producing cheaper power than most coal- and many gas-fired power plants (Figure 4).

Figure 4: Levelised costs of electricity (constant 2019 US dollars per kWh)

Source: CCC, 2020

⁵ See Section 3.127 of the OBR's Fiscal Risks Report, 2021. It should also be noted that the compositional affects from the transition on net revenues (for example losses in vehicle excise duty VED revenues) can be compensated by changes in tax rates and regimes. But the impact on the public finances from changes in the underlying growth of consumption, wages, profits, and employment are harder to offset without adding distortions to the economy.

The important lesson from Figure 4 is not just that renewable energy now competes with fossil fuels (net of infrastructure and subsidies), but rather how this transition came about and what lessons can be learned to stimulate further innovations. The pace and extent of cost reductions required a series of several interconnected, amplifying feedback mechanisms. These include:

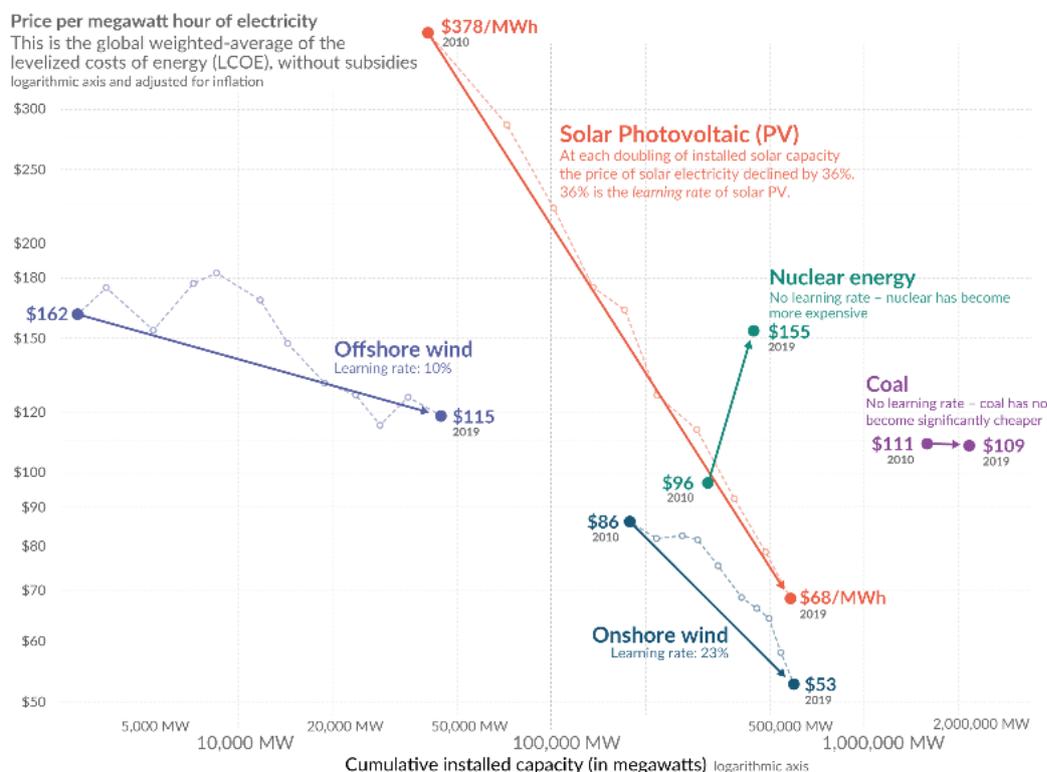

- **Learning-by-doing.** With deployment, lessons are learned on how to manufacture, distribute, instal, run and maintain equipment more efficiently.
- **Economies of scale in production and distribution.** Unit cost fall as production and distribution ramps up once large, fixed costs are incurred.
- **Network and coordination effects.** This reflects the greater advantages of moving in tandem with others, such that the gains are higher the more economic agents are taking similar action.
- **Sector spill-overs.** Not only have sustainable technologies been shown to have predictably higher cost-reducing learning rates, but they have also been shown to have positive productivity spill-overs into other sectors of the economy. Using data on 1 million patents and 3 million citations, Dechezleprêtre et al (2014) suggest that productivity enhancing spill-overs from low-carbon innovation are over 40 percent greater than from conventional technologies (in the fossil fuel energy production and transportation sectors).
- **Social and institutional feedbacks.** Acceptable standards of behaviour and social norms are liable to change (Ostrom 2000; Posner 1997).
- **Evolution of consumer behaviour.** Consumer tastes are key in the attribution of future value to goods and services and consumers routinely influence one another, leading to positive feedbacks and crowd effects and changing consumption patterns. The heterogeneity of real-world consumer behaviour is readily inferred from standard innovation diffusion theory where technology adoption typically follows s-shaped patterns starting with innovators and early adopters, through the majority to finally affect laggards (Mercure et al. 2021)
- **Expectations.** People's changing expectations with shape the nature and pace of change. Perception of new technologies as superior leads to behaviour change which itself facilitates their successful adoption (van der Meijden and Smulders 2017). Expectations that the cost of a net zero transition will be inevitable and affordable can become self-fulfilling (Zenghelis 2021a).

Figure 5 demonstrates how these economic phenomena interact to drive innovation and transition. Note that initially, low levels of installed capacity are associated with high costs. This means markets alone were highly unlikely to deliver the necessary transition. Early-on, government leadership (subsidies and signals) was needed to drive initial investments. Learning-by-doing and economies of scale drove efficiency gains as installed capacity grew. Notably, coal has not become significantly cheaper over the same time period. Instead, social norms and consumer behaviour have driven demand for renewable energy, and in many parts of the world, for the complementary purchases such as electric vehicles. Strong policy signals on the phase-out of internal combustion engines have further shaped expectations, and manufacturers are responding by increasing the range of EVs available on the market.

Whilst it remains to be seen whether the story of renewable energy is an exception – the timescales, cost profiles, and innovation pathways in other sectors may differ – it is clear that an early start, corresponding to the OBR net zero scenario, is therefore likely to cut the costs of transition and improve economic performance compared with delay and indecision. It may also be pivotal to shaping the long-term sustainability of the public finances.

Figure 5: Renewable electricity costs fall as installed capacity rises

Electricity from renewables became cheaper as we increased capacity – electricity from nuclear and coal did not

Source: IRENA 2020 for all data on renewable sources; Lazard for the price of electricity from nuclear and coal – IAEA for nuclear capacity and Global Energy Monitor for coal capacity. Gas is not shown because the price between gas peaker and combined cycles differs significantly, and global data on the capacity of each of these sources is not available. The price of electricity from gas has fallen over this decade, but over the longer run it is not following a learning curve.

6. Competitive position and macroeconomic context

The transition will also affect any advanced economy's competitive position in changing world markets. Most European countries are small to medium sized open economies. Productivity and growth over long time periods will be driven by comparative as well as absolute advantages in new markets, and these are not set in stone but are shaped by policy. This goes beyond comparing absolute investment and operating costs.

Falling behind on policies and investments may induce significant displacement of high productivity (and high productivity growth) activities to other countries, if the world shifts to low carbon resource efficient markets (e.g. as a result of global policies hostile to high carbon activities and undercutting technologies outcompeting high carbon incumbents).

Hidalgo et al (2007) and Mealy and Teytelboym (2021) use network analysis to demonstrate that it is easier for countries to become competitive in new green products that require similar production capabilities and know-how to existing sectors. This helps demonstrate how green transitions are highly path-dependent: countries which successfully invest early in green capabilities have greater success in diversifying into future green product markets. This also has potential implications for industrial policy seeking to develop comparative advantages in fast growing new sectors. The potential fiscal risks should be clear.

Other studies focus on “revealed technological advantage” to determine where opportunities for sustainable growth and recovery might reside. Martin et al (2020) compare broad categories of technologies and find that the UK is relatively specialised in wind and ocean energy, as well as biotechnology and pharmaceuticals. They argued that the returns to public investments in these technologies are likely to be disproportionately high (see also Stern and Valero 2021).

The impact of adopting policies to transition the economy to net zero, and associated risks, is a function of the broader global macroeconomic context. Recent evidence on productivity strongly suggests the world needs markedly higher investment (Zenghelis 2021). Weak private confidence has meant ex ante desired investment lagged desired saving for more than a decade, driving real risk-free interest rates to below zero.⁶

Negative rates in turn push the efficacy of monetary policy to its limits, fuelling asset price rises that disproportionately benefited the rich. A fundamental policy error following the crash of 2008 was introducing austerity programmes to balance budgets prematurely. Reduced public borrowing to invest exacerbated the problem of excess net saving (Auerbach and Gorodnichenko 2017). Research suggests European countries suffered a decade of lower growth than the US, which adopted a far more relaxed fiscal stance (Jordà and Taylor 2016).

7. Conclusion and policy imperatives

Climate change poses new risks which will affect the financial system, fiscal sustainability and sovereign debt markets. At the same time, attempts to meet agreed climate targets will require an unprecedented structural transformation of the global economy over the next two or three decades. The changing landscape of risks warrants new risk management and hedging strategies to contain climate risk and minimise the impact of asset stranding and asset devaluation. Yet, conditional on action being taken early, the opportunities from managing a net zero transition would substantially outweigh the costs.

Public investment in complimentary assets alongside supportive policies and institutions are prerequisites to ‘crowd in’ sustainable capacity and bolster the structural resilience of the economy. This historic growth opportunity has been reflected in large stimulus and recovery packages adopted in the EU, US and other advanced economies. Each has placed clean investment at its heart.

Yet the call for public investment to boost productive capacity, following an unprecedented government response to the global pandemic, understandably has raised concerns about fiscal space. Public debt relative to GDP is already close to historic highs in many European countries. Combined with record broad money supply growth it has also rekindled fears of the return of inflation (Haldane 2021).

These justifiable fears notwithstanding, the risks from higher public debt in the short term, are far lower than the likely benefits (Stern and Zenghelis 2021). There are increasing opportunities associated with a public drive to steer a zero-carbon economy which can crowd in investment and expand capacity. The IMF Fiscal Monitor for October 2020 argued that an additional £1 in public borrowing to invest in “job-rich, highly productive, and greener activities” would generate an

⁶ The term neutral refers here to the rate that would prevail when the economy is operating close to capacity, not requiring either a tight/loose monetary stance to contain/stimulate demand. It reflects underlying structural factors shaping preferences for desired savings and investment, rather than cyclical positions dictated by policy rates. It reflects a country's equilibrium real rate of interest in the long run. According to Rachel and Smith (2015), lower expectations for trend growth and shifts in desired savings and investment have driven a 400bps of the 450bps decline in the global long-term neutral rate since the 1980s. See Stern and Zenghelis (2021)

additional £2.7 of additional output (IMF 2020; Gaspar et al 2020). This marks scope for strong crowding-in. The markets agree: they continue to lend to governments at real interest rates which remain at near-record lows. The most promising way to bring down public debt in the medium term is to borrow to invest now (Chudik et al., 2017).

A fundamental feature of transition and climate change is that the infrastructure, skills and ideas of the last century can quickly become a liability. Resource- and carbon-intensive physical, human and knowledge assets risk becoming devalued or obsolete. Early indications suggest that this may already be affecting some asset prices, even as fossil fuels continue to play a key role in the economy. However, due to the difficulty of translating climate risks to financial risks, markets have been slow to respond. It is for this reason that the Financial Stability Board's Task Force for Climate Related Disclosure is calling for mandatory disclosure and stress testing of assets (TCFD 2017).

It is increasingly recognised that growth is not only compatible with sustainability, it requires it (Zenghelis 2021). Recent studies have highlighted the urgent need to strengthen the quality of natural assets (New Climate Economy 2018). They also point to numerous near-term opportunities associated with tackling particulate pollution, congestion, ill-health, biodiversity loss, inefficiency and waste and building more attractive, liveable cities. This is especially true after the COVID pandemic, which marks a period of dislocation and change affording a potential opportunity to lock in to pathways which create durable and resilient jobs (Stern et al 2020).

A recent survey of 231 economic experts from G20 countries, including central bank and finance ministry officials, found that major fiscal recovery packages that focussed on clean R&D spending, clean energy infrastructure, connectivity infrastructure, building upgrades, energy efficiency and investment in green spaces were considered best placed to boost long term growth (Hepburn et al. 2020).

Just and inclusive policies will lower transition costs

With many of the key barriers to the low carbon transition being political and behavioural, rather than technological and economic, policymakers recognise the need to act quickly and carefully to ensure that change is in the interest of the many. This means compensating, reskilling and retooling those who stand to lose out, enabling them to participate in the new economy and provide the jobs of the 21st century. It also means supporting overstretched consumers who may face higher charges to fund transitional infrastructure investment. Ensuring a just transition will be central to maintaining social cohesion (Robins et al. 2019).

So how big are transition risks? The correct answer is that it is 'endogenous' (Ekins and Zenghelis 2021). It depends on the choices and actions we take today and in the future. The longer we wait to manage that transition, the bigger the dislocation risks and the higher the adjustment costs. Understanding the processes which drive innovation, change social norms and build stronger institutions will help decision-makers steer growth in a manner that is not only cleaner and more secure, but also more innovative, competitive and productive. This reduces transition risk. By this logic, any optimism must be conditional. It requires credible and ambitious action in the near term to avoid catastrophic and irreversible environmental risk and unleash private ingenuity and finance to build a more efficient, innovative, and productive economy.
