**Abstract** The measurements of quasi-periodic oscillations (QPOs) provide a quite powerful tool to test the nature of astrophysical black hole candidates in the strong gravitational field regime. In this paper, we use QPOs within the relativistic precession model to test a recently proposed family of rotating black hole mimickers, which reduce to the Kerr metric in a limiting case, and can represent traversable wormholes or regular black holes with one or two horizons, depending on the values of the parameters. In particular, assuming that the compact object of GRO J1655-40 is described by a rotating black hole mimicker, we perform a  $\chi$ -square analysis to fit the parameters of the mimicker with two sets of observed QPO frequencies from GRO J1655-40. Our results indicate that although the metric around the compact object of GRO J1655-40 is consistent with the Kerr metric, a regular black hole with one horizon is favored by the observation data of GRO J1655-40.

## 1 Introduction

The first observations of gravitational waves by LIGO [1] and the first image of a black hole in the galaxy M87 [2] have ushered us into a new era of testing general relativity (GR) in the strong gravity regime. On the other hand, quasi-periodic oscillations (QPOs) are observed in the X-ray flux from black hole and neutron star X-ray binary systems, and detected as narrow peaks in the power density spectrum [3]. QPOs are believed to be associated with motion and accretion-related timescales in a region of order the Schwarzschild radius around the compact object, which makes QPOs excellent probes of the strong gravitational field regime [4–8]. In black hole systems, the observed frequencies of QPOs range from mHz to hundreds of Hz. While low frequency QPOs ( $\lesssim 30$  Hz) are commonly observed from black hole X-ray binaries [9], high frequency QPOs ( $\gtrsim 60$  Hz) are very rare. In fact, the Rossi X-ray Timing Explorer (RXTE), operational between 1996 and 2012, first detected high frequency QPOs in black hole systems [10, 11]. Interestingly, a pair of simultaneous high-frequency QPOs was first discovered in the X-ray flux from GRO J1655-40 by RXTE [12]. It was noted that the frequencies of the two high-frequency QPOs are in a 3:2 ratio, suggesting a resonance between orbital and epicyclic motion of accreting matter near the innermost stable circular orbit (ISCO) of black holes [13]. Later, three simultaneous QPO frequencies, consisting of two higher frequencies and one lower frequency, were also observed from the X-ray data of GRO J1655-40 [14].

On the theoretical side, various models have been proposed to explain QPOs by relating them to the orbital and epicyclic frequencies of geodesics, such as the relativistic precession model (RPM) [15], the tidal disruption model [16], the parametric resonance model [17], the resonance model [13, 18, 19], the warped disk oscillation model [20] and the non-axisymmetric disk oscillation model [21, 22]. With these models, the observation data of QPO frequencies

have been used to constrain the parameters of X-ray binary systems and test the nature of various gravity theories [23–37].

Particularly, it showed that the X-ray data of GRO J1655-40, especially the QPO triplet, fit nicely in the RPM, and the mass and spin of the compact object of GRO J1655-40 can be precisely determined [14]. Remarkably, the inferred mass is in great agreement with the dynamical mass measurement [23]. The RPM was originally proposed to explain QPOs in low-mass X-ray binaries with a neutron star [38], and later extended to systems with stellar-mass BH candidates [15]. In the RPM, QPO frequencies are assumed to be related to fundamental frequencies of a test particle orbiting a central object. The twin higher frequencies are regarded as the azimuthal frequency  $\nu_\phi$  and the periastron precession frequency  $\nu_{\text{per}}$  of quasi-circular orbits in the innermost disk region, respectively. The low-frequency QPO is identified as the nodal precession frequency  $\nu_{\text{nod}}$ , which is emitted at the same radius where the twin higher frequencies are generated.

On the other hand, curvature singularities can be formed during a gravitational collapse. It is commonly believed that singularities can be avoided through quantum gravitational effects. Consequently, since Bardeen proposed the first regular black hole [39], constructing and studying classical black holes without singularities have been a topic of considerable interest in GR and astrophysics communities due to their non-singular property [40–47]. Recently, Simpson and Visser proposed a static and spherically symmetric regular spacetime described by the line element (dubbed the SV metric henceforth),

$$ds^2 = - \left( 1 - \frac{2M}{\sqrt{r^2 + \ell^2}} \right) dt^2 + \left( 1 - \frac{2M}{\sqrt{r^2 + \ell^2}} \right)^{-1} dr^2 + (r^2 + \ell^2) (d\theta^2 + \sin^2 \theta d\phi^2), \tag{1}$$

where  $M \geq 0$  represents the ADM mass, and  $\ell > 0$  is a parameter responsible for regularizing the center singularity [48–50]. The most appealing feature of the SV metric (1) is that it can smoothly interpolate between a regular black hole for  $\ell < 2M$  and a wormhole for  $\ell \geq 2M$ . In the limit of  $\ell = 0$ , the SV metric reduces to the ordinary Schwarzschild spacetime. Subsequently, the properties of the SV metric were discussed, e.g., quasinormal modes [51], precessing and periodic geodesic motions [52], gravitational lensing [53–55] and shadows [56,57]. To make the SV metric more relevant to realistic situations, the SV metric (1) was generalized to a family of rotating black hole mimickers, dubbed the rotating SV metric, which may represent a rotating wormhole and a rotating regular black hole with one or two horizons [58]. The strong gravitational lensing and the shadows of the rotating SV metric have been investigated in [59,60], respectively.

In this paper, we test gravity with QPOs frequencies observed from GRO J1655-40 within the RPM for the rotat-

ing SV metric. The content of this paper is as follows. After we briefly review the RPM and the rotating SV metric in Sects. 2 and 3, respectively, the epicyclic frequencies of the rotating SV are computed in Sect. 3. In Sect. 4, we use the data of GRO J1655-40 to put constraints on the parameters of the rotating SV metric. Section 5 is devoted to our conclusions. Throughout the paper, we use units in which  $G = c = 1$ .

## 2 Epicyclic frequencies

In this section, we consider the timelike geodesic equations in a stationary and axially symmetric spacetime, and then derive the expressions of the epicyclic frequencies. The metric of a stationary and axially symmetric spacetime which satisfies the circularity condition is given by [61]

$$ds^2 = g_{tt}dt^2 + g_{rr}dr^2 + 2g_{t\phi}dtd\phi + g_{\theta\theta}d\theta^2 + g_{\phi\phi}d\phi^2, \tag{2}$$

where the metric  $g_{\mu\nu}$  is a function of  $r$  and  $\theta$ , and we drop the coordinate dependence of the metric functions to simplify the notation. For a massive particle travelling along a time-like world line  $x^\mu(\tau)$  with  $\tau$  being the proper time, the four-velocity  $U^\mu$  is defined by  $U^\mu = \dot{x}^\mu = dx^\mu/d\tau$ , which satisfies  $U^\mu U_\mu = -1$ . Due to the stationarity and axisymmetry, the metric (2) admits two Killing vectors,

$$\begin{aligned} K^\mu &= (\partial_t)^\mu = (1, 0, 0, 0) \quad \text{and} \\ R^\mu &= (\partial_\phi)^\mu = (0, 0, 0, 1). \end{aligned} \tag{3}$$

The two Killing vectors correspond to two conserved quantities of geodesic motion,

$$\begin{aligned} E &= -K_\mu \frac{dx^\mu}{d\tau} = -g_{tt}\dot{t} - g_{t\phi}\dot{\phi}, \\ L_z &= R_\mu \frac{dx^\mu}{d\tau} = g_{t\phi}\dot{t} + g_{\phi\phi}\dot{\phi}, \end{aligned} \tag{4}$$

which can be interpreted as the energy per unit mass and the angular momentum per unit mass along the axis of symmetry, respectively. In terms of  $E$  and  $L_z$ , one can express  $\dot{t}$  and  $\dot{\phi}$  as

$$\dot{t} = \frac{g_{\phi\phi}E + g_{t\phi}L_z}{g_{t\phi}^2 - g_{tt}g_{\phi\phi}}, \quad \dot{\phi} = \frac{g_{t\phi}E + g_{tt}L_z}{g_{tt}g_{\phi\phi} - g_{t\phi}^2}. \tag{5}$$

Using the above equations, we can rewrite  $U^\mu U_\mu = -1$  as

$$g_{rr}\dot{r}^2 + g_{\theta\theta}\dot{\theta}^2 = V_{\text{eff}}(r, \theta), \tag{6}$$

where the effective potential  $V_{\text{eff}}(r, \theta)$  is defined as

$$V_{\text{eff}}(r, \theta) = \frac{E^2 g_{\phi\phi} + 2EL_z g_{t\phi} + L_z^2 g_{tt}}{g_{t\phi}^2 - g_{tt}g_{\phi\phi}} - 1. \tag{7}$$

We consider a circular geodesic at  $r = \bar{r}$  on the equatorial plane with  $\theta = \pi/2$ , which means that the effective potential may develop a double root at  $r = \bar{r}$  on the equatorial plane, i.e.,  $V_{\text{eff}}(\bar{r}, \pi/2) = \partial_r V_{\text{eff}}(\bar{r}, \pi/2) = 0$ . Along the circular orbit, the angular velocity of the particle measured by an observer at infinity is defined by

$$\Omega_\phi = \frac{d\phi}{dt} = \frac{\dot{\phi}}{\dot{t}} = - \frac{g_{t\phi}E + g_{t\phi}L_z}{g_{\phi\phi}E + g_{t\phi}L_z} \Big|_{r=\bar{r}, \theta=\pi/2} \tag{8}$$

Solving  $V_{\text{eff}}(\bar{r}, \pi/2) = 0$  with Eq. (8) gives the specific energy and angular momentum of the particle,

$$E = - \frac{g_{tt} + g_{t\phi}\Omega_\phi}{\sqrt{-g_{tt} - 2g_{t\phi}\Omega_\phi - g_{\phi\phi}\Omega_\phi^2}} \Big|_{r=\bar{r}, \theta=\pi/2},$$

$$L_z = \frac{g_{t\phi} + g_{\phi\phi}\Omega_\phi}{\sqrt{-g_{tt} - 2g_{t\phi}\Omega_\phi - g_{\phi\phi}\Omega_\phi^2}} \Big|_{r=\bar{r}, \theta=\pi/2} \tag{9}$$

Solving  $\partial_r V_{\text{eff}}(\bar{r}, \pi/2) = 0$  for  $\Omega_\phi$ , one obtains the angular velocity of the particle,

$$\Omega_\phi = \frac{-\partial_r g_{t\phi} \pm \sqrt{(\partial_r g_{t\phi})^2 - (\partial_r g_{tt})(\partial_r g_{\phi\phi})}}{\partial_r g_{\phi\phi}} \Big|_{r=\bar{r}, \theta=\pi/2} \tag{10}$$

where the sign  $+/-$  corresponds to a prograde/retrograde orbit. The stability of the circular orbit is determined by the sign of  $\partial_r^2 V_{\text{eff}}(\bar{r}, \pi/2)$ , i.e.,  $\partial_r^2 V_{\text{eff}}(\bar{r}, \pi/2) > 0 \Leftrightarrow$  unstable and  $\partial_r^2 V_{\text{eff}}(\bar{r}, \pi/2) < 0 \Leftrightarrow$  stable. The transition between stable and unstable circular orbits, which is determined by  $\partial_r^2 V_{\text{eff}}(r_{\text{ISCO}}, \pi/2) = 0$ , is the ISCO, which is located at  $r = r_{\text{ISCO}}$  on the equatorial plane.

To derive the epicyclic frequencies associated with the circular orbit, we consider small perturbations of the orbit in both the radial and the vertical directions,

$$r(t) = \bar{r} + \delta r(t), \quad \theta(t) = \frac{\pi}{2} + \delta\theta(t) \tag{11}$$

Inserting Eq. (11) into Eq. (6) yields the differential equations for the perturbations  $\delta r(t)$  and  $\delta\theta(t)$ ,

$$\frac{d^2 \delta r(t)}{dt^2} + \Omega_r^2 \delta r(t) = 0, \quad \frac{d^2 \delta\theta(t)}{dt^2} + \Omega_\theta^2 \delta\theta(t) = 0, \tag{12}$$

where the frequencies of the oscillations are

$$\Omega_r^2 = - \frac{1}{2g_{rr}i^2} \frac{\partial^2 V_{\text{eff}}(r, \theta)}{\partial r^2} \Big|_{r=\bar{r}, \theta=\pi/2}, \quad \Omega_\theta^2$$

$$= - \frac{1}{2g_{\theta\theta}i^2} \frac{\partial^2 V_{\text{eff}}(r, \theta)}{\partial \theta^2} \Big|_{r=\bar{r}, \theta=\pi/2} \tag{13}$$

We then define  $\nu_\phi = \Omega_\phi/2\pi$ ,  $\nu_r = \Omega_r/2\pi$  and  $\nu_\theta = \Omega_\theta/2\pi$  as the azimuthal, radial and vertical epicyclic frequencies, respectively. The periastron precession frequency  $\nu_{\text{per}}$  and the nodal precession frequency  $\nu_{\text{nod}}$  are defined by  $\nu_{\text{per}} = \nu_\phi - \nu_r$  and  $\nu_{\text{nod}} = \nu_\phi - \nu_\theta$ , respectively.

### 3 Rotating Simpson–Visser metric

In [58], a rotating generalization of the static and spherically symmetric metric (1) has been constructed by employing the Newman–Janis procedure [62]. This stationary and axially symmetric metric can describe a rotating traversable wormhole and a rotating regular black hole with one or two horizons. In particular, the rotating SV metric reads

$$ds^2 = - \left( 1 - \frac{2M\sqrt{r^2 + \ell^2}}{\Sigma} \right) dt^2 + \frac{\Sigma}{\Delta} dr^2 + \Sigma d\theta^2 - \frac{4Ma \sin^2 \theta \sqrt{r^2 + \ell^2}}{\Sigma} dt d\phi + \frac{A \sin^2 \theta}{\Sigma} d\phi^2, \tag{14}$$

with

$$\Sigma = r^2 + \ell^2 + a^2 \cos^2 \theta,$$

$$\Delta = r^2 + \ell^2 + a^2 - 2M\sqrt{r^2 + \ell^2},$$

$$A = (r^2 + \ell^2 + a^2)^2 - \Delta a^2 \sin^2 \theta, \tag{15}$$

where  $a$  is the spin parameter. The rotating SV metric will reduce to the SV metric (1) if  $a = 0$  and to the Kerr metric if  $\ell = 0$ . Interestingly, the rotating SV metric is everywhere regular when  $\ell > 0$  [58].

The horizons of the rotating SV metric are determined by  $\Delta = 0$ , whose solutions are

$$r_\pm = \sqrt{\left( M \pm \sqrt{M^2 - a^2} \right)^2 - \ell^2} \tag{16}$$

As shown in [58], the phases of the rotating SV metric are determined by the existence of  $r_\pm$ . Specifically, the rotating SV metric represents

- a traversable wormhole:  $M < a$  or  $\ell > M + \sqrt{M^2 - a^2}$ ;
- a regular black hole with one horizon (RBH-I):  $M - \sqrt{M^2 - a^2} < \ell < M + \sqrt{M^2 - a^2}$  and  $M > a$ ;
- a regular black hole with two horizons (RBH-II):  $\ell < M - \sqrt{M^2 - a^2}$  and  $M > a$ ;
- there limiting cases: a one-way wormhole with a null throat when  $\ell = M + \sqrt{M^2 - a^2}$ , a regular black

**Fig. 1** Plots of the effective potential  $V_{\text{eff}}$  of a massive particle travelling on the equatorial plane with  $\theta = \pi/2$  as a function of radius  $r$  in a traversable wormhole with  $\ell = 12$  (left panel), a RBH-I black hole with  $\ell = 1$  (middle panel) and a RBH-II black hole with  $\ell = 0.08$  (right panel) for  $L_z = 25$  (red lines),  $L_z = 26$  (green lines) and  $L_z = 27$  (blue lines). We have  $M = 6$ ,  $a = 1$  and  $E = 1$ . The horizons of the RBH-I and RBH-II black holes are represented by orange dashed lines.

hole with one horizon and a null throat when  $\ell = M - \sqrt{M^2 - a^2}$  and an extremal regular black hole when  $M = a$ .

Substituting the rotating SV metric (14) into Eq. (7), one can obtain the effective potential  $V_{\text{eff}}$  for a massive particle in the rotating SV metric. Like a Schwarzschild black, we find that, for a massive particle with a large enough  $|L_z|$ ,  $V_{\text{eff}}$  possesses a minimum and a maximum on the equatorial plane, corresponding to a stable circular orbit and an unstable one, outside the event horizon of a black hole or in the each universe of a wormhole. As  $|L_z|$  increases, the two circular orbits move further away from each other. In Fig. 1, we plot  $V_{\text{eff}}$  as a function of  $r$  for various values of  $L_z$  in three cases, i.e., a traversable wormhole, a RBH-I black hole and a RBH-II black hole. Here without loss of generality, we have set  $M = 6$ ,  $E = 1$ ,  $a = 1$  and  $\theta = \pi/2$ . Note that the two universes of the wormhole are connected at  $r = \ell$ , where the effective potential has a cusp.

For a circular orbit at  $r = \bar{r}$  on the equatorial plane, substituting the rotating SV metric (14) into Eqs. (8) and (13) gives epicyclic frequencies in the rotating SV metric,

$$\begin{aligned}
 \nu_\phi &= \frac{1}{2\pi} \frac{M^{1/2}}{(\bar{r}^2 + \ell^2)^{3/4} \pm aM^{1/2}}, \\
 \nu_r &= \frac{\bar{r} \nu_\phi}{(\bar{r}^2 + \ell^2)^{1/2}} \\
 &\sqrt{1 - \frac{6M}{(\bar{r}^2 + \ell^2)^{1/2}} - \frac{3a^2}{(\bar{r}^2 + \ell^2)} \pm \frac{8aM^{1/2}}{(\bar{r}^2 + \ell^2)^{3/4}}}, \\
 \nu_\theta &= \nu_\phi \sqrt{1 \mp \frac{4aM^{1/2}}{(\bar{r}^2 + \ell^2)^{3/4}} + \frac{3a^2}{(\bar{r}^2 + \ell^2)}}, \tag{17}
 \end{aligned}$$

In the three cases, the effective potential always decreases to zero at infinity. For the traversable wormhole, the effective potential has one maximum and one minimum in each universe. For the RBH-I black hole, the effective potential has one maximum and one minimum outside the event horizon. The effective potential of the RBH-II black hole is similar to that of the RBH-I black hole

which can be used to constrain the four parameters  $\ell$ ,  $\bar{r}$ ,  $M$ , and  $a$  of the rotating SV metric. Here, the top/bottom row of the  $\pm$  and  $\mp$  signs corresponds to the orbit co-rotating/counter-rotating with the spacetime. To illustrate the dependence of the epicyclic frequencies on  $\ell$ , we plot  $\nu_\phi$ ,  $\nu_{\text{per}}$  and  $\nu_{\text{nod}}$  as a function of  $\ell$  for various values of  $a$  in Fig. 2, where  $M = 1$  and  $\bar{r} = 6$ . The prograde and retrograde cases are represented by solid and dashed lines, respectively. The left panel shows that, for a fixed  $a$ , the azimuthal epicyclic frequency  $\nu_\phi$  decreases with  $\ell$  increasing in both prograde and retrograde cases, whereas  $\nu_\phi$  of the prograde orbit is smaller than that of the retrograde orbit. The periastron precession frequency  $\nu_{\text{per}}$  is displayed in the middle panel, and also decreases as  $\ell$  increases for both prograde and retrograde orbits. Like  $\nu_\phi$ , the retrograde orbits have larger  $\nu_{\text{per}}$ . Note that retrograde circular orbits of radius  $\bar{r} = 6$  do not exist when  $\ell$  is small enough. However, as shown in the right panel, the nodal precession frequency  $\nu_{\text{nod}}$  of the prograde/retrograde orbits decreases/increases as  $\ell$  increases for a given  $a$ . More interestingly, when  $a > 0$ ,  $\nu_{\text{nod}}$  of the retrograde orbits is negative while that of the prograde orbits is positive. Note that the nodal precession is defined as the precession of the ascending node, which is the point where the orbit passes through the plane of reference, e.g., the equatorial plane in our paper. If the SV metric is spherically symmetric with  $a = 0$ , the orbital plane of a particle remains fixed in space, and hence the nodal precession  $\nu_{\text{nod}}$  vanishes, which can be seen from Fig. 2. However for the rotating SV metric with a nonzero  $a$ , a particle in a prograde/retrograde orbit has been shown to have a positive/negative nodal precession  $\nu_{\text{nod}}$ , which means that the orbital plane rotates in the same/opposite direction as the direction of the SV metric's

**Fig. 2** Plots of the azimuthal epicyclic frequency  $\nu_\phi$  (left panel), the periastron precession frequency  $\nu_{\text{per}}$  (middle panel) and the nodal precession frequency  $\nu_{\text{nod}}$  (right panel) of prograde (solid lines) and retrograde (dashed lines) orbits at  $\bar{r} = 6$  as a function of  $\ell$  for  $a = 0$  (red lines),  $a = 0.4$  (green lines) and  $a = 0.8$  (blue lines) in the rotating

SV metric with  $M = 1$ . The  $a = 0$  case corresponds to the SV metric, which has  $\nu_{\text{nod}} = 0$  due to spherical symmetry. Except  $\nu_{\text{nod}}$  with  $a = 0$ , the magnitudes of  $\nu_\phi$ ,  $\nu_{\text{per}}$  and  $\nu_{\text{nod}}$  decrease as  $\ell$  grows with a fixed  $a$ . For the retrograde orbits in the rotating SV metric with  $a > 0$ , the values of  $\nu_{\text{nod}}$  are shown to be negative

rotation. Interestingly, it is well-known that the nodal precessions of a satellite in prograde and retrograde orbits around Earth have opposite signs [63]. Finally, it is noteworthy that the ISCO radius  $r_{\text{ISCO}}$  is determined by [58],

$$r_{\text{ISCO}}^2 + \ell^2 - 6M\sqrt{r_{\text{ISCO}}^2 + \ell^2} \pm 8a\sqrt{M\sqrt{r_{\text{ISCO}}^2 + \ell^2}} = 3a^2, \tag{18}$$

where  $+/-$  is associated with the prograde/retrograde ISCO.

#### 4 Constraining rotating Simpson–Visser metric by quasi-periodic oscillations

In this section, we use the RPM along with the QPO frequencies from GRO J1655-40 to put constraints on the parameters of the rotating SV metric. GRO J1655-40 is an X-ray binary, consisting of a primary star and a compact companion [64]. The measurement of the X-ray spectrum was found to exhibit type-C low-frequency QPOs and simultaneous high-frequency QPOs, which are observed in pairs and therefore dubbed lower and upper high-frequency QPOs [12, 14]. In particular, we consider two sets of QPOs with the observed frequencies based on the RXTE observations [14],

$$\begin{aligned} \nu_{1U} &= 441 \text{ Hz}, & \sigma_{1U} &= 2 \text{ Hz}, \\ \nu_{1L} &= 298 \text{ Hz}, & \sigma_{1L} &= 4 \text{ Hz}, \\ \nu_{1C} &= 17.3 \text{ Hz}, & \sigma_{1C} &= 0.1 \text{ Hz} \end{aligned} \tag{19}$$

and

$$\nu_{2U} = 451 \text{ Hz}, \quad \sigma_{2U} = 5 \text{ Hz},$$

$$\begin{aligned} \nu_{2L} &= - , \\ \nu_{2C} &= 18.3 \text{ Hz}, \quad \sigma_{2C} = 0.1 \text{ Hz}. \end{aligned} \tag{20}$$

In the RPM, three simultaneous QPO frequencies are generated at the same radial coordinate in the accretion disk. The upper high-frequency QPOs correspond to the azimuthal epicyclic frequency  $\nu_\phi$ , the lower high-frequency QPOs to the periastron precession frequency  $\nu_{\text{per}}$ , and the low-frequency QPOs to the nodal precession frequency  $\nu_{\text{nod}}$ . Moreover, it is reasonable to assume that the above two sets of QPOs result from two circular orbits of different radii, i.e.,  $\bar{r}_1$  and  $\bar{r}_2$ . In short, we have five free parameters: the mass  $M$ , the spin parameter  $a$ , the  $\ell$  parameter, and the radii  $\bar{r}_1$  and  $\bar{r}_2$  corresponding to the QPOs with three frequencies and two frequencies, respectively. To obtain the estimate of the five parameters from the observed QPO frequencies, we follow the procedure used in [28, 33, 34] and perform a  $\chi$ -square analysis with

$$\begin{aligned} \chi^2(M, a, \ell, \bar{r}_1, \bar{r}_2) &= \frac{(\nu_{1\phi} - \nu_{1U})^2}{\sigma_{1U}} + \frac{(\nu_{1\text{per}} - \nu_{1L})^2}{\sigma_{1L}} \\ &+ \frac{(\nu_{1\text{nod}} - \nu_{1C})^2}{\sigma_{1C}} \\ &+ \frac{(\nu_{2\phi} - \nu_{2U})^2}{\sigma_{2U}} + \frac{(\nu_{2\text{nod}} - \nu_{2C})^2}{\sigma_{2C}}, \end{aligned} \tag{21}$$

the minimum of which,  $\chi_{\text{min}}^2$ , occurs at the best estimate of  $M$ ,  $a$ ,  $\ell$ ,  $\bar{r}_1$  and  $\bar{r}_2$ . The range of the parameters at a confidence level (C.L.) is determined by the interval  $\chi_{\text{min}}^2 + \Delta\chi^2$ . In the case of five degrees of freedom, the intervals with  $\Delta\chi^2 = 5.89, 11.29$  and  $17.96$  correspond to 68.3%, 95.4% and 99.7% C.L., respectively, which are the probability inter-

**Fig. 3** Estimate of the mass  $M/M_{\odot}$ , of the spin parameter  $a/M$  and of the parameter  $\ell/M$  of the rotating SV metric, which describes the spacetime around the compact object in GRO J1655-40, from interpreting the observations of QPOs in the RPM. Specifically, the best-fit values (red dots) and the contour levels of  $1\sigma$  (orange lines),  $2\sigma$  (green lines) and  $3\sigma$  (blue lines) for the parameters are shown in the  $\ell/M$ - $a/M$  (left panel),  $\ell/M$ - $M/M_{\odot}$  (middle panel) and  $M/M_{\odot}$ - $a/M$  (right panel) planes. In the yellow and blue regions, the rotating SV metric represents regu-

lar black hole solutions with one and two horizons, respectively. The observed frequencies of the QPOs in GRO J1655-40 are consistent with a Kerr black hole (the rotating SV metric with  $\ell = 0$ ), but they also allow for large deviations from the Kerr black hole solution. In particular, a regular black hole with one horizon is favored over the other phases of the rotating SV metric, e.g., a regular black hole with two horizons and a traversable wormhole

vals designated as 1, 2, and 3 standard deviation limits, respectively.

Computing  $\chi^2$ , we find  $\chi^2_{\min} = 0.195$  and obtain the best fits of the parameters of the rotating SV metric within 68.3% credibility,

$$M/M_{\odot} = 5.305^{+0.041}_{-0.028}, a/M = 0.286^{+0.003}_{-0.002}, \ell/M = 0.347^{+0.011}_{-0.347}. \tag{22}$$

Note that our result is consistent with the measurement of the mass  $M$  by optical and infrared observations, which give  $M = 5.4 \pm 0.3M_{\odot}$  [23]. We present the best estimate and the  $1\sigma$ ,  $2\sigma$  and  $3\sigma$  contour levels of  $M/M_{\odot}$ ,  $a/M$  and  $\ell/M$  in Fig. 3, where the yellow/blue regions represent the RBH-I/RBH-II phases of the rotating SV metric. As shown in the left and middle panels, while the hypothesis that the compact object of GRO J1655-40 is described by a Kerr black hole is consistent with the interpretation of the QPOs' data in the RPM, significant deviations from the Kerr metric are allowed. In fact, the best-fit values are in the parametric region of the RBH-I phase, and the regions within 1-, 2- and 3-standard deviation limits are almost in the RBH-I region. Therefore, the observation of GRO J1655-40 favors a regular black hole with one horizon if the compact object of GRO J1655-40 is described by the rotating SV metric. The best-fit values of the radii of the circular orbits associated with the two sets of QPOs are found to be  $\bar{r}_1 = 5.669M = 1.1304r_{\text{ISCO}}$  and  $\bar{r}_2 = 5.563M = 1.1094r_{\text{ISCO}}$ , respectively, where  $r_{\text{ISCO}} = 5.105M$  is the innermost stable circular orbit evaluated for the rotating SV metric with the best-fit values (22). Consequently, the two circular orbits responsible for gener-

ating the two sets of QPOs lie in the close vicinity of the ISCO, and hence are in the strong-field region of the rotating SV metric.

### 5 Conclusions

In this paper, we explored potential deviations from the GR predictions of astrophysical black holes using QPOs observed in the power density spectrum of GRO J1655-40. Specially, we modelled the spacetime around the compact object of GRO J1655-40 by the rotating SV metric, and interpreted the observed QPOs within the RPM, which relates the QPO frequencies to epicyclic frequencies of geodesics. The rotating SV metric reduces to a Kerr black hole in the limit of  $\ell = 0$ , and possesses multiple phases, e.g., a regular black hole with one or two horizons and a traversable wormhole. To test the nature of the compact object of GRO J1655-40, we performed a  $\chi^2$  analysis by fitting the QPO frequencies computed in the RPM with the observations of two sets of QPOs from GRO J1655-40. Our results show a preference towards a regular black hole with one horizon compared to the Kerr black hole predicted in GR.
