Abstract: While ultrafast spectroscopy with photocurrent detection was almost unknown before 2012, in the last three years a number of research groups from different fields have independently developed ultrafast electric probe approaches and reported promising pilot studies. Here we discuss these recent advances and provide our perspective on how photocurrent detection successfully overcomes many limitations of all-optical methods, which makes it a technique of choice when device photophysics is concerned. We also highlight compelling existing problems and research questions and suggest ways for further development, outlining the potential breakthroughs to be expected in the near future using photocurrent ultrafast optical probes.

TOC figure:

Ultrafast transient absorption methods and their multidimensional extensions are currently well-developed approaches to study electronic and structural dynamics of optoelectronic nanosystems like organic, organic-inorganic hybrid or quantum-dot photovoltaic devices, biological light-conversion systems or electrochemical cells. Some successful examples include elucidation of charge separation and transport pathways in organic materials,¹⁻⁶ observation of structural^{7,8} and vibrational⁹ dynamics as well as elucidation of correlation of multiple excited states and coherent phenomena involved.^{10,11} The essence of the approach comes down to using a sequence of two or more sub-picosecond optical pulses. First, pump pulse(s) bring the system into the excited state, leading to the modulation of the system's optical properties. These photoinduced changes affect the probe pulse(s) intensity, as they pass through the sample. Therefore, the detection of the out-coupled probe field as a function of delay between pump and probe pulses provides an opportunity to resolve the dynamics of the optoelectronic system in time.

Despite the long history of development and a broad choice of particular technique modifications, most varieties of transient absorption (TA) methods suffer from a range of limitations when applied to optoelectronic systems and devices:

(i) At low excitation pulse energies, the photoinduced modulation in optical properties can be small and insufficient to provide a detectable variation in optical density. To tackle this problem, high pump intensities are usually used to boost the signal, which typically scales linearly with the excitation intensity. However, this may cause photodegradation. It was also proven that high photon fluxes are unsuitable for some optoelectronic materials and devices that should be studied at 'working condition' illumination.^{12,13} Finally, multi-step absorption to higher-lying states at moderate fluence may display apparent linear intensity behaviour, but lead to unexpected population products.¹⁴

(ii) The observed variations of optical properties are broad and featureless, and can be similar for different photoexcited states, complicating the interpretation of the results. Also the optical cross-sections of some transition can be much weaker compared to the others, making the signatures of the most important processes (for example charge dynamics that determine device performance) hidden behind other trivial but strong spectroscopic responses.¹⁵

(iii) The detection scheme in any transient absorption technique requires outcoupling of probe light. This makes these methods of limited use for samples with high optical density in the probe region and for certain types of device. In addition, highly scattering samples are

inaccessible for one-color TA-type experiments unless sophisticated techniques like phase cycling¹⁶ or double modulation¹⁷.

(iv) Due to the all-optical detection nature, the spatial resolution of TA methods is limited by the size of the probe beam. Therefore, even in optical microscopy configurations the typical dimension of resolved features cannot reach below a few hundred nm, which may be insufficient for nanomaterial characterization.

Transient absorption spectroscopy, therefore, is an effective and well-developed tool to address charge dynamics in model systems like solutions or homogeneous films. However, all the restrictions mentioned above make this method of limited use for addressing time-resolved dynamics in optoelectronic devices and functional systems at working conditions.

Figure 1. The concept of ultrafast experiment with photocurrent detection. The pump pulses bring the system to the excited state and the push pulses modulate the excited-state dynamics. The detection is done by observing the effect of the push on the device performance.

In this perspective, we review recent developments in device-based ultrafast spectroscopies with photocurrent (PC) detection (**Fig. 1**). In this method, a sequence of short optical pulses first brings the system to the excited state and then modulates the excited-state dynamics, while the effect of modulation is observed through the device performance. Though this approach was not widely used before 2012, a number of research groups from different fields have independently developed electric probe schemes and reported promising pilot studies in the last three years. Here we show that the ultrafast spectroscopy with PC detection successfully overcomes the limitations of all-optical methods mentioned above, and that it becomes a technique of choice when (nano)devices are concerned. Our paper also reviews

existing problems on the way to further development and outlines the potential breakthroughs to be achieved in the near future.

Towards ultrafast photocurrent spectroscopy

A promising alternative to all-optical methods in application to optoelectronic devices can be hybrid spectroscopic methods with electrical detection. The most simple and widely used example of this approach is PC excitation spectroscopy. In this technique, an actual optoelectronic device is illuminated by a continuous-wave (CW), tunable, monochromatic light source, and the produced PC is measured as a function of photon energy. Alternatively, a broadband interferometric realization of this technique can be used.¹⁸ PC spectroscopy is widely used to study the nature of photoexcitations in semiconductors. From an application point of view, it is an essential technique to unravel the charge generation process for the optimization of solar cells based on novel materials.¹⁹ It is particularly useful for systems where photocarriers are not produced directly by inter-band transitions, but are mediated by a precursor states such as excitons in quantum-confined or molecular semiconductors. PC detection directly probes those states via their excitation spectral lineshapes.¹⁸ Being purely absorption-sensitive, PC spectroscopy easily eliminates scattering and reflection artefacts, which gives it an outstanding dynamic range, sufficient for the identification of very low concentrations of defect states and intermolecular interactions. The main limitation of the conventional PC spectroscopy is that it is a steady-state technique incapable to address and resolve in time the dynamics of the excited states.

To our knowledge, the first successful attempt to resolve excited-state electronic dynamics in molecular systems using PC detection was reported in 1981 by Lukin and co-workers.²⁰ They used (**Fig. 2a**) a combination of two laser sources to identify an intermediate state responsible for the PC generation after anthracene ionization in an electrochemical device. Though Lukin et al. used two CW light sources, the lifetime of the intermediate state formed after the illumination with 347-nm laser (trapped electron in solution) was sufficiently long to allow its sequential re-excitation by a 694-nm source, leading to a very substantial (40 times) increase in PC. The application area for the developed two-color CW PC spectroscopy was limited to the systems with a very long-lived intermediate excited states and this method did not attract broad interest despite of its clear potential.

To elucidate the dynamics of intermediate states with shorter lifetimes, a pulsed modification of the technique was developed.²¹ For simplicity, we will from now on address

this technique as the 2-pulse PC (2PPC) method. In a 2PPC experiment, an optoelectronic device is illuminated by a sequence of two – so called, pump and push -- laser pulses interacting with the active material in the device. The result of these interactions is detected by observing the variations in the current flow through the device as a function of time delay between the pump and push and their spectra. 2PPC combines the sensitivity and device relevance of electronic methods with the excitation selectivity and ultrafast time resolution of optical techniques.

Figure 2. Early two-colour PC spectroscopy studies. (a) The setup for two-color PC spectroscopy on electrochemical devices. Reproduced from ²⁰ with permission Elsevier, 2015. Note the elegant stability-control solution with a reference cell. (b) Comparison between transient absorption, 2-pulse photoluminescence and 2PPC measurements from ²² with permission APS, 2015.

Later Frankevich et al ²³ exploited advances in solid-state ultrafast lasers and applied ultrafast 2PPC techniques to investigate charge dynamics in organic nanodevices. This pioneering study featured sub-ps time resolution and discovered the existence of precursor states for the photocarrier formation in organic semiconductors. The development has triggered

substantial interest and inspired a more detailed work from the Feldman group.²² These studies were the first to compare different ultrafast techniques including transient absorption, 2PPC and 2-pulse photoluminescence (**Fig. 2b**). As seen from the figure, even all above measurements are performed on the same device with identical pulses the observed kinetics are similar for transient absorption and photoluminescence as those reflect purely exciton dynamics but are different for 2PPC response. This reveals that 2PPC is sensitive to a sub-ensemble of excited states particularly critical for efficient device performance.²⁰ Despite the initial success, the visible-push realisation of the 2PPC method used by Frankevich et al. and Muller et al. have not acquired wide recognition and application. We believe the main reason behind this was that visible push pulses were used in these techniques, which brings several issues for the interpretation of data. Primarily, the high (1-2 eV) photon energy of visible push pulses is sufficient to generate charge carriers in organic semiconductors through both sub- and above-gap states, which leads to high background currents. Furthermore, such strong visible push pulses strongly perturb the excited-state dynamics. Both factors complicated the interpretation of data and limited the use of the technique.

2-pulse photocurrent spectroscopy with IR push pulse

The limitation of using high-energy push photons in 2PPC methods was overcome with an IR push pulse that is not resonant with the absorption of the system in the ground state.²⁴ Gentle and targeted IR re-excitation allowed application of this technique to study charge separation and charge trapping dynamics in organic and hybrid optoelectronic systems. Initially, IR 2PPC was applied to identify loss channels in organic photovoltaic cells, by switching optically the electronic states of the molecules.²⁴⁻²⁶ The 2PPC kinetics presented in the **figure 3a**, reflect the probability to enhance the dissociation of bound interfacial charge transfer state using the energy from additional IR photon.²⁴ This study observed for a range of organic photovoltaic systems that charge transfer state formation is the efficiency limiting step. It also demonstrated that the dissociation of bound carriers requires a transition from a local polaronic level to a delocalised ‘band’ state, which can be induced by a ~0.5-eV photon. The opportunities this new method provided have been applied to different material systems, including multicomponent organic photocells,²⁷ oxide-based hybrid optoelectronic devices,^{28,29} and colloidal quantum dot p-i-n diodes.³⁰

The application of IR push pulses potentially provides an opportunity to access vibrational modes and their coupling to electronic dynamics. Using 2PPC approach it has been recently demonstrated experimentally that the performance of an organic optoelectronic system can be

controlled by selectively exciting vibrational modes of the molecules involved in charge transport using a pentacene/C₆₀ photoresistor as a model system.³¹ When addressing vibronic phenomena, a selective excitation of different vibrational modes is required. This can be achieved using narrow-band IR pulses^{32,33} at the expense of time resolution, or by applying an ultrafast interferometry approach,^{34,35} which allows for a precise control over the time/frequency-domain structure of the IR optical pulses. The latter approach was used in 2PPC study where an interferometric sequence of two ultrafast mid-IR laser pulses created a coherent superposition of molecular vibrational motions inside the active layer of a device and then vibrational excitation was correlated with the device performance. Importantly, this interferometric approach combines sufficient $<10\text{ cm}^{-1}$ frequency resolution to identify vibrational modes with a 100-fs time resolution despite using the broadband IR-push spectrum. In fact, a spectral bandwidth of at least 300 cm^{-1} is essential for keeping ultrafast (sub-100-fs) time resolution needed for observation of nuclear and electronic dynamics.

Figure 3. (a) 2PPC transients reflecting the recombination dynamics of bound electron-hole states in a range of organic photovoltaic devices, adapted from²⁴ with permission AAAS, 2015 (b) Frequency-resolved effect of IR irradiation on the photoconductivity of pentacene molecular crystal. Vibrational (narrow) and electronic (broad) response are observed. 30-ps time delay was set between the visible and IR pulses. Adapted from³¹ with permission Nature Publishing Group, 2015.

When the PC signal is resolved as a function of push photon energy, two different types of responses can be identified (Fig. 3b). One is a broad response, which has a weak dependence on the IR photon energy. This component is associated with a low-energy polaronic transition,⁴ and the effect of IR excitation is probably similar to one observed for charge-transfer states in organic photovoltaic devices.²⁴ At the same time, a narrow-band response is observed only at certain push-photon frequencies, e.g. $\sim 1300\text{ cm}^{-1}$ or $\sim 1445\text{ cm}^{-1}$. These frequencies correspond to the vibrational modes of the studied organic semiconductor (pentacene). This indicates that the observed increase in PC originates from the coupling between vibrational and electronic degrees of freedom, so-called vibronic phenomena. Both the experiment and theoretical calculations demonstrate that different non-equilibrium geometries and atomic motions have dissimilar effects on the charge dynamics. For example, the vibrations along the long axis of pentacene molecules (e.g. $\sim 1445\text{ cm}^{-1}$ mode) lead to a larger increase in charge hopping rate than the molecular motions along the short axis (e.g. 1300 cm^{-1} mode). Such mode-selective ‘vibrational control’ of charge dynamics opens a number of new opportunities, including utilization of vibronic phenomena for ultrafast switching of organic devices and identification of charge transport mechanisms and pathways in (bio)molecular junctions.

2D photocurrent spectroscopy

2D electronic spectroscopies are the extensions of visible-region transient absorption methods that permit identification of homogeneous and inhomogeneous spectral lineshape contributions and can reveal microscopic inter-chromophore couplings. In a 2D spectroscopic measurement, the response of a system driven by multiple electromagnetic fields is recorded in a multidimensional frequency or time space. This involves exciting the sample with a sequence of phased ultrafast laser pulses, typically three or four depending on the adopted geometry, and picking up the nonlinear signal with the appropriate phase relationship. In the context of photocarrier generation dynamics, the potential to identify interstate couplings is key to investigate energy and charge transfer phenomena that eventually lead to photoconversion. Because of this, coherent optical spectroscopy has seen intensive development during the last decade, shedding key insights on a wide variety of phenomena, such as energy and electron transfer dynamics in photosynthetic systems,³⁶⁻³⁸ in addressing local conformations of nucleotides in DNA constructs,³⁹ in excited-state energy transfer of exciton-coupled molecular dimers in biological membranes,^{40,41} in coherent response of the optically created excitations in semiconductors and semiconductor nanostructures⁴²⁻⁴⁴ in probing

excitons in molecular dimers and aggregates⁴⁵⁻⁴⁹ and finally multi-polariton correlations in inorganic-semiconductor optical microcavities,⁵⁰ just to give a few examples of note.

Experimentally, 2D spectroscopy is most commonly implemented using a non-collinear geometry of the excitation beams.^{46,51-53} Within this approach, three non-collinear laser pulses interact with the sample inducing a third-order polarization, which radiates in a phase-matched direction, with the amplitude and phase of that radiation detected by means of spectral interferometry with a fourth replica pulse (heterodyne detection).⁵⁴

As PC detection does not require outcoupling and spatially separating light pulses, a different experimental scheme has been recently implemented, based on four collinear femtosecond pulses and acousto-optic phase modulation.⁵⁵ The first pulse sets the system in a coherent non-equilibrium superposition of states. The second pulse converts this superposition to a population in the excited state, which keeps the phase of the superposition state. The third pulse generates again a coherent superposition of states, which the fourth pulse converts to an observable fourth-order population. The signal being measured might, then, be considered as proportional to this excited-state fourth-order population. This collinear experimental approach was developed by Marcus and coworkers to investigate the non-linear optical response of fluorescent systems like atomic Rb vapor.⁵⁵ Recently, the technique was extended by Nardin et al. to detect PC instead of the luminescence in GaAs quantum wells produced for 2D electron-gas studies,⁵⁶ followed by Karki et al. to address carrier multiplication processes in PbS solar cells.⁵⁷ This modification makes the technique particularly valuable for the investigation of charge carrier generation dynamics in photocells because it offers direct access to the physical quantity of interest, i.e. PC, at the operating regime of the devices.

One advantage of the collinear approach with PC detection comes from the employment of acousto-optic modulation to achieve the phase-locking condition of the four excitation pulses, with a pulse sequence depicted in Fig. 4(a). The phase modulation scheme determines a PC signal evolving in time at specific frequencies, thus allowing to isolate the 4th order population contribution to the overall signal by phase-sensitive detection. Each measurement, obtained by scanning the time variables t_{21} and t_{43} (see Fig. 4(a) for a definition of these inter-pulse delay times) simultaneously produces four maps: the in-phase and the in-quadrature ones for the rephasing and non-rephasing frequencies.⁵⁸ The maps so obtained in the time domain are, finally, converted in the energy domain by Fourier-transforming the time variables t_{21} and t_{43} (see Fig. 4(a) for a definition of these inter-pulse delay times) and recorded as a function of the population time, t_{32} . It is worth noting that, in contrast to the partitioning resonant dispersive

and absorptive features between the real and imaginary parts of the linear optical response, the rephasing and non-rephasing spectra contain mixed absorptive and dispersive contributions.

The work by Karki et al., which addressed carrier multiplication processes in solar cells based on colloidal semiconductor quantum dots,⁵⁷ demonstrated a sub-picosecond evolution of the lineshape of the 2D PC-detected spectra from absorptive to dispersive character, interpreted as a time-dependent shift of the resonant transition energies during exciton multiplication. The specific sensitivity accessible through directly probing the PC is illustrated in Fig. 4, which compares the components of 2D total correlation spectra as measured by both PC and fluorescence detection.⁵⁷ The PC data were acquired on the photocell, whereas the photoluminescence spectra were measured on a colloidal suspension sample under the same excitation conditions. As is evident, the two probes provide remarkably different spectra. In particular, the PC-detected spectrum shows a dispersive line shape, whereas the fluorescence detected one exhibits primarily absorptive features. It was speculated⁵⁷ that the observed responses are different because the multiple excitons in quantum dots do not contribute efficiently to luminescence, because of their rapid non-radiative Auger recombination. On the other hand, in the photocell, the electron-hole pairs in the multiple exciton states separate within a few picoseconds, thus contributing to a significant PC quantum yield. The results reported by Karki et al. provide an eloquent example of how different final observables, in that case photoluminescence and PC, provide insights on the dynamics through the different excited state pathways in optoelectronic materials and devices.

Figure 4. (a) Schematic of the pulse sequence used in a 2D-PC experiment.

(b)-(e) Reproduced from Ref⁵⁷ with permission Nature Publishing Group, 2015. Real part of the 2D total correlation spectra (that is the sum of the rephasing and non-rephasing signals) as measured by (b) PC on a PbS colloidal quantum dot photocell and (c) by photoluminescence on a PbS colloidal suspension. The qualitative forms of the 2D line shape in each case reproduced from calculations are reported in (d) and (e).

Another example of implementing PC detection in 2D coherent techniques probes a photovoltaic device based on the benchmark polymer-fullerene blend PCDTBT:PCBM.⁵⁹ Fig. 5 (a) displays J-V curves measured under solar illumination and under pulsed femtosecond excitation. In particular the latter curve was acquired under the same excitation conditions as the 2D maps shown in Fig. 5 (b)-(e). The comparison reported in Figure 5(a) illustrates yet another relevant advantage of the multidimensional PC detected spectroscopy over TA methods: this PC detected variant of 2D spectroscopy probes the photocarrier generation process in photovoltaic devices under actual working conditions.

Figure 5. (a) J-V curve on an organic photovoltaic device under pulsed femtosecond excitation and under illumination with a solar simulator. 2DPC spectra on the same device: (b)-(c) rephasing signal, (d)-(e) non-rephasing signal. Reproduced from Ref⁵⁹.

Fig. 5 shows the PC detected 2D real and imaginary spectra on this photocell: rephasing (Fig.5(b)-(c)) and non-rephasing spectra (Fig.5(d)-(e)) were acquired simultaneously using a two-channel lock-in amplifier. It highlights a powerful feature of the application of PC detection in the context of 2D coherence spectroscopies, which measure correlation spectra related to the full complex nonlinear permittivity function, composed of absorptive and dispersive contributions, in the PC excitation spectrum. This is an important aspect to evaluate the evolution of charged photoexcitations in excitonic solar cells: the details of the photocarrier production dynamics are contained in the complex permittivity function, as underlined eloquently by the work of Karki et al.⁵⁷ These data represent, to the best of our knowledge, the first attempt to measure 2DPC spectra on an organic based photocell. Beyond the field of photovoltaic devices based on novel materials, 2DPC might also be relevant in the study of single nano-structures where PC have already been reported.^{60,61} Moreover, this technique could be particularly helpful in the investigation of polariton many-body correlations in inorganic quantum-well Fabry-Pérot microcavities where electrodes can be applied and PC easily detected.

Ultrafast photocurrent spectroscopy down to single molecule level

An important advantage of electrical methods is their outstanding sensitivity and capacity to probe local phenomena. One well-established example of electrical spatially sensitive method is scanning tunnelling microscopy (STM), which uses current detection to observe objects as small as single atoms or organic molecules. Such sensitivity is hardly achievable by all-optical methods due to the complexities with overcoming optical diffraction limit, relatively low absorption cross section, and photobleaching. At the same time, single molecules can be stable enough to conduct well-detectable currents for long periods of time, providing large statistics and high accuracy of measured values. Unfortunately, conventional STM-type techniques are not suitable for observing fast (sub- μ s) dynamics of nanosystems, due to the limitations of electrical circuits. The accessible time window is usually defined by the time constants of current injection and the response time of electric amplifiers.^{62,63} To resolve this limitation, ultrafast optical pulses can be used to modulate the current flow. There have been already a number of successful developments along this path. Femtosecond lasers were used to gate the STM tip,⁶⁴ to switch the transmission lines⁶⁵ or to modulate the tunnelling current by the tip and/or sample electronic excitation,⁶⁶ which allowed in some exceptional cases to reach a few-ps dynamics regime. Unfortunately, the outlined approaches have not yet become a robust solution due to the complexity of the experimental approach.

An interesting development for ultrafast STM have been recently proposed by Cocker and co-workers using THz spectroscopy instrumentation.⁶⁷ In their approach, the STM junction bias was modulated by irradiating the scanning probe tip with sub-ps terahertz pulses. This modulation introduced strong tunnelling-current pulses in an STM only for the period of THz pulse transiting the tip area, therefore gating the nanojunction between the tip and the sample in different moments of time. When combined with an additional, optical ‘dynamics trigger’ pulse, the terahertz STM provided simultaneous <500-fs time resolution and nanometre (2-nm) imaging resolution under ambient laboratory conditions, which was sufficient, for example, to image ultrafast carrier capture into a single InAs quantum dot. We note that, despite the very different optical range and current generation mechanism, the concept of THz STM is quite similar to the 2PPC/2DPC described above. All the methods first use visible pump pulse(s) to create the excited state of interest and then THz or Vis/IR ‘push’ samples the dynamics of the excited states after a controllable delay time. The practical difference comes for the fact that ‘reference’ current is generated by visible light in 2PPC and by THz light in THz STM which implies that different modulation schemes for lock-in detection should be employed.

Figure 6. (a-b) The concept of a THz ultrafast tunneling microscope. (c) A representative time-resolved tunneling transient provide by such microscope, which features sub-ps time and 2-nm spatial resolution. Reproduced from ⁶⁷ with permission Nature Publishing Group, 2015.

The idea of using tunnelling current is not limited to THz modulation and STM approach. There is an ongoing progress in applying electric detection and multipulse techniques to study different types of molecular junctions, down to the single-molecule level,⁶⁸ or any other type of the system that is conductive on the nanoscale. The above-mentioned studies illustrate the strength of ultrafast spectroscopy with PC detection when individual nano-dimension systems or devices are concerned. This approach provides a unique opportunity to combine the outstanding sensitivity of electrical measurements with unprecedented time resolution of ultrafast optical techniques.

Information provided by photocurrent vs optical detection

Based on the existing studies it is possible to make a few general conclusions about the type of responses that can be observed in ultrafast PC detection spectroscopies (Fig. 1). Firstly, only the processes affecting charge generation can be observed using PC detection. This allows neglect of many ‘background’ responses, such as coherent artefacts, scattering and photochromic effects, narrowing down the observable to the dynamics of interest. Secondly, the stimulated emission (SE) and ground-state bleach (GSB) responses are well observable with ultrafast PC methods. Particularly, SE signals can be interpreted in a similar way as they are in TA data, just by inverting the sign of the response.²⁰ Indeed, whereas the all-optical methods register the increase of transmitted light, the PC methods should register the drop in the device output as fewer excited states are formed in the sample. Thirdly, the origins of photoinduced absorption (PIA) responses are quite different in TA and PC. As the lifetime of higher-lying excited states in most optoelectronic materials is very short, the effect of the system dynamics due to the additional absorbed photon is determined by the thermalization pathway to the first excited state. If after the push pulse the system repopulates back the same state it was excited from, no changes will be observed in the long-term charge dynamics and in PC output. However, if the push pulse leads to the different or modified excited state, the charge dynamics are likely to be affected and the device performance will vary. Both, negative and positive PIA responses have been observed in ultrafast PC experiments. While the former are usually indicative of releasing a bound charge carrier, the latter are sign of enhanced bimolecular processes like exciton-exciton annihilation or recombination.²⁴ From this perspective, the positive PIA signals provide the most valuable information for the development of the optoelectronic devices, as they help to identify bottleneck states in the excited-state dynamics. Positive PC signals present the direct evidence that the device

performance can be improved if additional energy is given to the system at the certain moments of time, which can serve an efficient feedback parameter for device optimization.

Conclusions and perspective for the future

PC detection schemes in ultrafast optical probes have a distinct advantage in terms of sensitivity compared to optical probe techniques. Namely, when photocarriers are generated efficiently, this detection scheme has the potential to detect every photoexcitation event. This is certainly the case in semiconductor nanostructures,⁵⁶ but is also the case in molecular systems that are designed for applications in photodetectors and solar cells. PC detection opens the door for implementations that are simply not possible using optical detection schemes, such as single-molecule nonlinear optical probes under low-intensity illumination conditions representative of solar light. For example, we envision the development of single-molecule multidimensional spectroscopy that exploit the extraordinarily sensitivity of scanning probe techniques.

The opportunities presented by PC detection schemes will clearly facilitate the investigation of photosynthetic processes in natural systems with detail that goes beyond what is achievable with all-optical nonlinear probes such as four-wave mixing implementations of multidimensional spectroscopies. This is because a key product of the photosynthetic reaction – photocharge – can be isolated and interrogated. We highlight recent breakthroughs in processing of native pigment proteins in device architectures that probe PC. For example, Friese et al. have recently exploited the high quantum efficiency of photosynthetic pigment-proteins by incorporating them directly in bio-electronic devices.⁶⁹ These consist of bacterial reaction centres and light-harvesting-1 complexes, self-assembled on an electrochemically roughened silver electrode. Due to enhanced light absorption facilitated by moderate plasmonic effects from the rough surface, this bio-hybrid nanostructured architecture displays peak PC of $>165 \mu\text{A cm}^{-2}$, solely derived from the photosynthetic material, under one-sun illumination, and up to three-fold higher currents under more intense illumination.⁶⁹ We anticipate that non-incremental progress in the understanding of natural light harvesting mechanisms in diverse native protein environments will be achieved as a result of the opportunities presented by ultrafast PC probes.

Finally, the opportunity to examine the evolution of the complex permittivity function via PC probes in multidimensional excitation techniques promise breakthroughs in the

understanding of photocarrier generation in state-of-the-art thin-film solar cells, such as emerging perovskite technologies. Measurement of this optical response over ultrafast timescales provides a key window into the materials physics amongst the most relevant for solar energy conversion – how are charges that can do work generated by solar light? Our perspective is that PC-detected optical probes will play a central role in unraveling these underlying physics.

Quotes to highlight in the paper:

- Ultrafast spectroscopy with PC detection successfully overcomes the limitations of all-optical methods and becomes a technique of choice when (nano)devices are concerned.

- Only the processes affecting charge generation can be observed using PC detection. This allows to neglect many ‘background’ responses, such as coherent artefacts, scattering and photochromic effects, narrowing down the observable to the dynamics of interest.
- Photocurrent detection opens the door for implementations that are simply not possible using optical detection schemes, such as single-molecule nonlinear optical probes under low-intensity illumination conditions representative of solar light.
