

Anomalous-Diffusion-Assisted Brightness in White Cellulose Nanofibril Membranes

Matti S. Toivonen, Olimpia D. Onelli, Gianni Jacucci, Ville Lovikka, Orlando J. Rojas, Olli Ikkala,* and Silvia Vignolini*

The understanding of the interaction between light and complex, random structures is the key for designing and tailoring the optical appearance and performance of many materials that surround us, ranging from everyday consumer products, such as those for personal care, paints, and paper, to light diffusers used in the LED-lamps and solar cells. Here, it is demonstrated that the light transport in membranes of pure cellulose nanofibrils (CNFs) can be controlled to achieve bright whiteness in structures only a few micrometers thick. This is in contrast to other materials, such as paper, which require hundreds of micrometers to achieve a comparable appearance. The diffusion of light in the CNF membranes is shown to become anomalous by tuning the porosity and morphological features. Considering also their strong mechanical properties and biocompatibility, such white coatings are proposed as a new application for cellulose nanofibrils.

Whiteness is achieved when light is elastically scattered multiple times in random media.^[1] In general terms, the higher the number and the strength of the scattering events, the brighter the material appears.^[2] This simple principle explains why many commercially available white products, such as paints and sun creams, are typically formulated with high refractive index nanoparticles (e.g., TiO₂) as scattering enhancers.^[3] The use of such promoters improves the scattering efficiency of the material, and therefore reduces the volume required to obtain

fully opaque white coatings. However, the widespread use of TiO₂ particles as scattering enhancers, for example in food, cosmetics, and paper, has recently raised serious health and environmental concerns.^[4,5] Therefore, there is a real need to improve scattering efficiency using more sustainable and biocompatible materials.^[6,7]

In nature, scattering is optimized in biopolymeric structures by the intricate design of the morphology and the spatial arrangement of the scattering elements.^[8–10] In particular, dense random networks of nanofibers, due to the intrinsic polydispersity and anisotropy of the scattering elements, allow efficient packing and represent a particularly convenient strategy

to optimize brightness in thin coatings. Fibrillar nanomaterials, such as cellulose nanofibrils (CNFs), are therefore promising candidates due to their inherent morphology, excellent mechanical performance, wide availability, renewability, and biocompatibility.^[11–15] However, paradoxically, research on the optical properties of CNF-based materials has focused on the optimization of their transparency.^[16,17] Therefore, the possibilities of using CNFs to construct an efficient scattering medium have not been explored, although recently their potential for high-haze diffusive optical elements for optoelectronic applications has been recognized.^[18]

Here, we demonstrate a scalable and versatile approach for light management in the CNF membranes. By inducing appropriate porosity and tuning the size distribution of the CNFs in the membranes, we are able to modify their nanostructure and easily produce membranes with completely different optical appearance: from thick, highly transparent membranes to thin, bright white ones. The produced membranes are mechanically stable as they retain the amorphous domains and hemicelluloses of natural cellulose fibers, in contrast to films based on cellulose nanocrystals which are significantly more brittle.^[6] Finally, we observe that the light transport in strongly scattering CNF membranes unexpectedly undergoes anomalous diffusive behavior.

The membranes with different scattering properties are obtained by fractionating a CNF dispersion with a wide distribution of fibril diameters via a sequential centrifugation procedure, as schematically illustrated in **Figure 1a**. The finest fibrils (i.e., smallest diameters) are first isolated from the original CNF dispersion by repeated centrifugation, collection of the supernatant, dilution, and homogenization. Subsequently, the same procedure is repeated at a lower centrifugal speed in order to isolate a dispersion of slightly thicker fibrils, which is

Figure 1. a) Schematic illustration of the preparation procedure of the fractionated CNF dispersions by differential centrifugation. b) Photograph of the resulting fractionated CNF dispersions after dilution to an equal concentration (0.9 g L^{-1}); left to right: finest, medium, and coarsest fibrils. Photographs of the compact CNF films (left) and the $\approx 10 \text{ }\mu\text{m}$ thick, porous membranes of CNFs dried from octane (right) when using c) the finest, d) the medium, and e) the coarsest fibrils. The outer edges of the membranes and the compact films are $\approx 1 \text{ cm}$ off the paper underneath while the edge at the center of the image is in contact with the paper. In panel (c), the text remains fully legible underneath the transparent membrane made from the first supernatant, whereas in panel (e) the text cannot be resolved from under the white membrane fabricated from the coarsest fibrils. The semitransparent membrane in panel (d) is the intermediate case. Masses of the compact CNF films and the corresponding porous membranes are 9.43 and 9.35 in panel (c), 9.53 and 9.11 in panel (d), and 8.34 and 7.95 mg in panel (e).

referred to as “medium fibrils” in the rest of the text. Finally, the sediment is collected, diluted, and homogenized. The fibrils in this last dispersion are referred to as “coarsest fibrils” in the following discussion. The presented sequential centrifugation process results in the three dispersions of fibrils, Figure 1b. For a fixed concentration, the turbidity of the dispersions correlates with the expected average fibril size. The distribution of the fibril diameters for the three dispersions is estimated by atomic-force microscopy, see Figures S1 and S2, Supporting Information. By measuring the diameters of more than 500 fibrils of each dispersion, we observe that their distributions follow, in first approximation, a log-normal statistics with a long tail, especially for the coarsest fibrils. The mean (and respective standard deviation) of the log-normal distributions of the fibril diameters in the three dispersions are 4.2 (2.7), 5.6 (3.2), and 19.5 (13.2) nm, going from the finest to the coarsest fibrils.

The porous membranes from the fractionated CNF dispersions are then prepared as described in an earlier work.^[19] In summary, the dispersion is vacuum filtered into a wet gel cake, followed by solvent exchange from water to 2-propanol, and further to octane, after which the gel cake is slowly dried in ambient conditions. The thickness of the membranes is controlled by the volume of dispersion filtered. For qualitative

comparison, photographs of the resulting porous membranes of equal thickness ($\approx 10 \text{ }\mu\text{m}$) prepared from the dispersions of the finest, medium, and coarsest fibrils are shown in Figure 1c–e (right-hand side of the photographs). The membranes prepared from the finest, medium, and coarsest fibrils are referred to as the “transparent,” “semitransparent,” and “white” porous membranes, respectively. The solvent exchange step is crucial for the porosity, and the consequent whiteness. For comparison, dense CNF films prepared from an equal volume of the corresponding dispersions which have been dried directly from water without the solvent-exchange process are displayed in Figure 1c–e (left-hand side of the photographs). The thicknesses of the dense, water-dried films are approximately half of those of the porous, octane-dried membranes, while the masses and lateral dimensions of the samples are nearly the same, indicating that the density of the films dried from water is approximately double of the porous membranes dried from octane. The reason for the densification of the CNF films upon drying from water is the combination of the capillary pressure of the evaporating water and the disruption of the hydrogen bonding network at the intersections of fibrils by water,^[20] as also known from the Campbell effect in papermaking.^[21] When the solvent is exchanged to octane, the hydrogen bonding

network between the fibrils is no longer disrupted by the solvent and the fibrils can be considered physically crosslinked, thus allowing the microstructure to resist the capillary pressure without collapsing.^[19,22,23]

The densities of the porous membranes are comparable and in the range $(0.81 \pm 0.16) \text{ kg m}^{-3}$. However, the porosity characterization by nitrogen physisorption revealed a different distribution of pore sizes. The transparent membranes show the highest specific surface area $(190 \pm 4) \text{ m}^2 \text{ g}^{-1}$ and smallest pores, followed by the semitransparent membranes with a lower specific surface area $(175 \pm 6) \text{ m}^2 \text{ g}^{-1}$ and slightly larger pores, while the white membranes show the lowest specific surface area $(122 \pm 3) \text{ m}^2 \text{ g}^{-1}$ and the largest pores. The pore size distributions obtained by nitrogen physisorption are shown in Figure S3, Supporting Information, and those estimated by image analysis from the cross-sectional scanning electron microscopy (SEM) images are shown in Figures S4 and S5, Supporting Information.

Total reflection spectra for the three types of the membranes at a thickness of $\approx 9 \mu\text{m}$ are reported in Figure 2a. Additional spectra for different thicknesses and a discussion of the wavelength dependence of the scattering properties are reported in Figure S6, Supporting Information. It is important to notice, that the white membrane—which is only $9 \mu\text{m}$ thick—exhibits a high broadband reflectivity (60–80%) for most of the visible range, reaching up to 90% for the shorter wavelengths, with a wide-angular scattering distribution, see Figure S7, Supporting Information. In comparison, common filter paper reflects only $\approx 50\%$ of the incident light even though its thickness is $160 \mu\text{m}$ (Figure S6, Supporting Information). Thus, the white membranes can be considered to be between 20 and 30 times more efficient opacifiers than filter paper.

To fully characterize the light transport in such systems, the total transmittance is measured as a function of the sample

thickness: we fabricate different membranes and, for each type, the optical response is characterized in 5–6 samples. Figure 2b shows that the light transport in the transparent membrane can be described by diffusion approximation theory,^[24] with a scattering mean free path of about $13.5 \mu\text{m}$ which is similar to that of paper ($13\text{--}22 \mu\text{m}$).^[6,10] Surprisingly, the diffusion approximation, which generally describes the behavior of the majority of scattering materials, fails to describe the data obtained for the other two membranes. Therefore, to explain the experimental results we adopt an extended formalism, which describes the light transport in superdiffusive and subdiffusing systems,^[25,26] where the total transmittance (T) scales with the sample thickness (L) as^[27]

$$T = \frac{1}{1 + AL^{\alpha/2}} \quad (1)$$

where A is a constant which depends on the scattering mean free path, the extrapolation length (a parameter that accounts for the internal reflections at the boundaries of the sample) and the absorption (the latter is negligible for cellulosic fibers),^[25,26,28,29] and α is a parameter that describes the diffusion behavior, see the Supporting Information. Notably when $\alpha = 2$, the scaling behavior is equivalent to the one in the standard diffusion approximation.^[24] As mentioned above, the data for the transparent samples are nicely fitted with $\alpha = 2$, while those for the two other membranes α is smaller than two. More specifically, we obtain $\alpha = 1.35 \pm 0.10$ and $A = 0.14 \pm 0.01$ for the semitransparent membrane, and $\alpha = 1.34 \pm 0.15$ and $A = 0.65 \pm 0.10$ for the white one. The details of the fitting routines and the formula used for the fit are presented in the Supporting Information and in Figure S8, Supporting Information.

To further understand the anomalous diffusive behavior of the samples and the unusual scaling law, we analyze the

Figure 2. Optical characterization of the three types of membranes. a) Total reflectance spectra at an approximate thickness of $9 \mu\text{m}$. b) Total transmittance at 500 nm as a function of sample thickness. The transmittance data series have been fitted according to Equation (1) by least-square regression (black lines). The transparent membranes (black squares) show a behavior very close to normal diffusion, $\alpha = (2.00 \pm 0.20)$ and $A = (0.004 \pm 0.005)$. As the presence of inhomogeneity increases in the semitransparent membranes (green triangles), the transmittance decays more steeply, $\alpha = (1.35 \pm 0.10)$ and $A = (0.14 \pm 0.01)$. For the white films (blue circles), $\alpha = (1.34 \pm 0.15)$ and $A = (0.65 \pm 0.10)$. The gray lines indicate the upper and lower bound for the value of the α parameter.

morphology of the membranes by SEM (Figure 3; Figures S4 and S5, Supporting Information) and nitrogen physisorption (Figure S3, Supporting Information). The typical anisotropy (i.e., transversely isotropic in-plane orientation of fibrils) of the CNF-based materials is observed for all membranes when comparing the top-view SEM images (Figure 3a–c) and the cross-section exposed by either uniaxial tensile fracture (Figure 3a–c) or by cryomicrotoming in cyclohexane and freeze-drying (Figures S4 and Figure S7, Supporting Information).^[22,30]

The SEM images reported in Figure 3a,d show that the transparent membranes are composed of a homogenous network of fine fibrils interspaced by small air voids. The pore size distribution clearly peaks around 30 nm (Figure S3, Supporting Information), whereas the average diameter of the fibrils is ≈ 4 nm (see Figure S2a, Supporting Information). From the morphological analysis and scattering cross-section calculations

(Figure S10, Supporting Information) we infer that the scattering in this case is mainly caused by the presence of the small air pores.

In contrast, in the case of the semitransparent membranes (Figure 3b,e), we observe in the SEM images a certain number of significantly larger pores. This is confirmed by the broader distribution of pore sizes, extending up to 700 nm, as observed by nitrogen physisorption (Figure S3, Supporting Information) and image analysis of the cross-sectional SEM (Figures S4 and S5, Supporting Information).

Similarly, in the SEM images of white membranes (Figure 3c,f; Figures S4 and S9, Supporting Information), we recognize several anisotropic large pores (up to thousands of nanometers), as confirmed by the porosity characterization (Figures S3 and S5, Supporting Information). In this case, the main fraction of the volume is occupied by the network of fine fibrils interspaced by

Figure 3. SEM images of: a–c) top surfaces of membranes and d–f) their corresponding cross-sectional fracture surfaces. The images show: a,d) transparent, b,e) semitransparent, and c,f) white membranes. The layered structures observed in the cross-sectional fracture surfaces are likely to be caused by the fracture process and are not present in the material prior to deformation,^[20] as supported by the cross-sections exposed by cryomicrotoming and freeze-drying shown in Figure S9, Supporting Information.

small pores. However, individual thicker fibrils (100–500 nm) are also sparsely embedded in this matrix in less dense regions.

We therefore speculate that the anomalous light transport for the semitransparent and white membranes is induced by the combination of the anisotropy of the scatterers (i.e., in-plane orientation of fibrils and pores, see Figures S4, S5, and S9 in the Supporting Information), and the rather wide distribution of sizes of both pores and fibrils, which consequently leads to a sparse spatial distribution of the stronger scatterers.

To further demonstrate that the observed anomalous diffusion of light is not merely due to artifacts introduced in the sample preparation (e.g., due to the dependence of the morphological features on sample thickness), a speckle statistic experiment is performed.^[31] The speckle patterns produced by the laser light transmitted through the investigated samples is imaged and recorded at more than 2000 separate locations (see the Experimental section in the Supporting Information and Figures S12 and S13, Supporting Information). To better

understand the data, we compare the response of white CNF membranes with standard filter paper (which is known to be a conventional diffuser with $\alpha = 2$ and scattering mean free path $\approx 18 \mu\text{m}$ at the wavelength used).^[6]

When light is transmitted through a standard diffusing sample, the individual speckle pattern varies between different sample locations but on average the radius (here measured by the full-width at half-maximum of the intensity) and intensity of the patterns are roughly constant as the light transport properties are the same across the specimen. In contrast, for an anomalously diffusive sample, the difference in speckle patterns between different sample locations is greater as the light paths can differ significantly depending on the local characteristics of the specimen, as shown in the literature.^[27,31] As expected, the speckle statistics differ greatly for the white CNF membrane as compared to white filter paper (see Figure 4a,b). The high degree of spatial and intensity variability between the different speckle patterns from different locations on the

Figure 4. Statistical analysis of the speckle patterns for the white CNF membrane (blue, anomalous light diffusion) in comparison to standard filter paper (red, normal diffusion). a) Distribution of the radii, R , of the speckle images normalized to their average R_{average} . b) Distribution of the intensity, calculated as the ratio between the maximum intensity I_{max} and the total image intensity I_{tot} . For filter paper both histograms show a narrow distribution, as expected for a normally diffusive medium. In contrast, the population is considerably wider for the white CNF membranes, as expected for anomalous transport. c) A scheme of a skewed random walk in which light (in red) is scattered more often in areas where the CNFs (in white) are more densely packed.

sample further confirms the anomalous diffusive behavior of the CNF system. For the standard diffusive samples, the radii and intensities of the speckle patterns are fairly constant at different positions, while for the white CNF membranes a broad distribution of values is observed (note that the radii and intensity have been normalized for better comparison). The speckle pattern intensities are inversely correlated with their radii as shown in Figure S14, Supporting Information.

Therefore, we speculate that the observed anomalous diffusion response in white and semitransparent CNF samples is due to three main factors: (i) the inhomogeneity in scattering strength due to the polydispersity of the fibrils (here we reasonably assume that each fibril can be considered a single scattering center); (ii) the inhomogeneity in the spatial distribution of fibrils, which could introduce longer steps between scattering events (Figure S9, Supporting Information); (iii) the anisotropy of the system due to in-plane orientation of the fibrils and anisotropic pores,^[22,30] which implies that light propagation and scattering proceed differently when occurring across the plane or parallel to the plane of the membrane, see scheme in Figure 4c. We feel confident of excluding that the intrinsic birefringence of cellulose (i.e., refractive index of 1.539–1.596 along the fiber and 1.519–1.538 in the transverse direction) contributes strongly to this effect, as this would generate only negligible differences in the scattering cross-section (see the calculations in Figure S10 and the measured transmittance of s- and p-polarized light in Figure S11, both in the Supporting Information).^[32–34]

In conclusion, we report a cellulose-based system in which it is possible to manipulate the light transport by simply tuning the morphology and the distribution of the CNF fibrils in the porous membranes. A transition from standard to anomalous diffusion is observed in the disordered photonic nanostructures when larger anisotropy in the fibril distribution was introduced. Even though further optimization by fine-tuning of the porosity and of the diameters distribution of the fibrils could lead to even thinner and brighter white membranes, we already obtain extremely high scattering efficiency in only few micrometer thickness,^[6,9] and the white membranes can be considered between 20 and 30 times more efficient scatterers than white filter paper. We believe that our observation showcases the potential of using CNFs and anomalous diffusion to produce next-generation efficient bright sustainable and biocompatible white materials.
