(Received xx; revised xx; accepted xx)

The stability of steady convective exchange flow with a rectangular planform in an unbounded three-dimensional porous medium is explored. The base flow comprises a balance between vertical advection with amplitude A in interleaving rectangular columns with aspect ratio $\xi \leq 1$, and horizontal diffusion between the columns. Columnar flow with a square planform ($\xi = 1$) is found to be weakly unstable to a large-scale perturbation of the background temperature gradient, irrespective of A , but to have no stronger instability on the scale of the columns. This result provides a stark contrast with two-dimensional columnar flow (Hewitt *et al.* 2013, *J. Fluid Mech.* **737**, 205–231), which, as A is increased, is increasingly unstable to a perturbation on the scale of the columnar wavelength. For rectangular planforms with $\xi < 1$, a critical aspect ratio is identified, below which a perturbation on the scale of the columns is the fastest growing mode, as in two dimensions. Scalings for the growth rate and the structure of this mode are identified, and are explained by means of an asymptotic expansion in the limit $\xi \rightarrow 0$. The difference between the stabilities of two-dimensional and three-dimensional exchange flow provides a potential explanation for the apparent difference in dominant horizontal scale observed in direct numerical simulations of two-dimensional and three-dimensional statistically steady ‘Rayleigh–Darcy’ convection at high Rayleigh numbers.

1. Introduction

The study of convection in porous media has blossomed in recent years, in part due to its relevance for the long-term fate of geologically sequestered CO_2 in underground aquifers (Huppert & Neufeld 2014). Convection in porous media plays a role in numerous other geophysical processes, including the mixing of brackish groundwater or the extraction of geothermal energy (Phillips 2009). It also provides a relatively tractable non-linear system for the study of chaotic dynamics, instabilities, and structure formation, because of the relative simplicity of Darcy’s law, which is linear, rather than the full Navier–Stokes equations (Nield & Bejan 2006).

Statistically steady Rayleigh–Bénard convection has long provided a canonical setting for the study of convective dynamics and heat transport. The porous analogue consists of a sealed fluid-saturated porous medium, heated at the base and cooled at the top, which we will subsequently refer to as a ‘Rayleigh–Darcy’ cell (although the names of Horton & Rogers (1945) and Lapwood (1948), amongst others, have also been linked with this system). The dynamics of flow in a Rayleigh–Darcy cell are strongly dependent on the Rayleigh number Ra , which is a dimensionless ratio of the driving buoyancy forces and the dissipative effects of fluid viscosity and thermal diffusion in the system. When the Rayleigh number is large ($Ra > O(10^3)$), the flow is dominated across most of the domain by a remarkably ordered columnar exchange flow of hot and cold fluid. Near the upper and lower boundaries, heat is carried away from thin thermal boundary layers into this

ordered interior flow by high-wavenumber ‘protoplumes’, which exhibit vigorous episodic bursting and time-dependent dynamics (Otero *et al.* 2004; Hewitt *et al.* 2012, 2014).

The interior columnar flow has an average horizontal wavenumber k that increases with the Rayleigh number, and the mechanism that controls this dependence has been the subject of some investigation (Hewitt *et al.* 2013; Wen *et al.* 2013, 2015). Numerical simulations in two dimensions presented by Hewitt *et al.* (2012) showed that the interior exchange flow varies only weakly in time, and is increasingly well described by a simple, steady ‘heat-exchanger’ solution of the governing equations. This flow comprises a balance between vertical advection along a background linear temperature gradient with horizontal diffusion between alternating columns of ascending and descending fluid. Hewitt *et al.* (2012) extracted an approximate scaling for the wavenumber of this flow of $k \sim Ra^{0.4}$ over the range $1300 \leq Ra \leq 4 \times 10^4$. Multiple sets of simulations were used to arrive at this scaling, both to check that there was no discernible effect of aspect ratio and to obtain an estimate of the statistical uncertainty in the measurements of k from the Fourier spectrum. More recent numerical simulations by Wen *et al.* (2015) broadly confirmed these observations, and extended the parameter range to $Ra \leq 99763$. At the highest values of Ra , they found that the interior flow becomes so well ordered that flows can become ‘locked’ with different numbers of interlacing plumes, and can persist in such a state for a very long time. As such, multiple simulations for the same value of Ra gave rise to different numbers of plumes, or different discrete wavenumbers, which suggests that caution is required when extracting an average relationship $k(Ra)$ over this higher range of Ra .

In an attempt to shed light on the physical basis for the scaling of $k(Ra)$, Hewitt *et al.* (2013) investigated the stability of unbounded heat-exchanger flow in a two dimensional porous medium. They found that the flow is always unstable, and that the most unstable mode for large Ra takes the form of a pulsatile perturbation on the scale of the columns. To apply these results to a finite domain, they formulated a simple marginal-stability balance between the timescale for growth of the instability and the timescale for advection across the height of the Rayleigh–Darcy cell. This scaling argument results in a prediction of $k(Ra)$ that is consistent with the numerical data, and a hypothesized asymptotic scaling of $k \sim Ra^{5/14}$.

In three dimensions, numerical simulations of flow in a Rayleigh–Darcy cell indicate a slightly stronger scaling for the dominant horizontal wavenumber of approximately $k \sim Ra^{0.5}$ (Hewitt *et al.* 2014). Again, the structure of the interior appears to adopt a simple heat-exchanger form, although the dominant horizontal planform of the flow is not clear. It is important to note that the numerical data in three dimensions is rather more sparse than in two dimensions, and does not extend to such large values of Ra . While this makes it even more difficult to be confident of, for example, precise exponents or planforms, the data does appear to show a distinctly stronger scaling for the wavenumber than in two dimensions.

In this paper we study the stability of unbounded, steady, single-mode ‘heat-exchanger’ flow with a rectangular planform in a three-dimensional porous medium. While a main aim of the study is to try to shed light on the difference between the observed scalings for $k(Ra)$ in two and three dimensions, we also find an unexpected richness in the stability properties of the rectangular planform of columnar flow, and explore this in some detail.

We note that a key weakness of this approach as a means of understanding the scaling $k(Ra)$ is that it is based on the stability properties of unbounded flow. In particular, it does not account explicitly for the vigorous dynamics of mixing and episodic flushing by protoplumes near the upper and lower boundaries. Wen *et al.* (2015) noted this issue and explored an alternative approach in two dimensions by tracking, and then examining the

stability of, exact, steady, non-linear solutions of the governing equations in a Rayleigh–Darcy cell at high Ra . They found that, in general, the dominant mode of instability was strongly localized to the boundaries, which corresponds to the growth of protoplumes there. We will return to the findings of Wen *et al.* (2015) in the discussion in §5.

This paper is laid out as follows. In §2, we outline the equations, the heat-exchanger base flow, and the scalings of the problem. In §3, we present numerical solutions for square and rectangular planforms. In §4, we explore the limit of long thin rectangles, for which the growth rate of the most unstable mode approaches the equivalent two-dimensional result, and derive an asymptotic description for the mode in this limit. Finally, in §5 we discuss the possible application of these results to the structure of three-dimensional Rayleigh–Darcy convection.

2. Setup

2.1. Governing equations and base flow

We consider convective flow in a homogeneous and unbounded three-dimensional porous medium. The flow \mathbf{u} is incompressible and satisfies Darcy’s law. The density ρ of the fluid is linearly related to the temperature T , which is assumed to be locally equilibrated between the solid and fluid phases of the medium and satisfies an advection–diffusion transport equation. These equations are given by

$$\nabla \cdot \mathbf{u} = 0, \quad \mathbf{u} = -\frac{K}{\mu} [\nabla p + \rho g \hat{\mathbf{z}}], \quad (2.1a, b)$$

$$\rho = \rho_0 (1 - bT), \quad \bar{\phi} \frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T = D \nabla^2 T, \quad (2.2a, b)$$

where K is the permeability of the medium, μ is the viscosity of the fluid, g is the gravitational acceleration, $\hat{\mathbf{z}}$ is the unit upwards vertical direction, ρ_0 is a reference density, b is the coefficient of thermal expansion, and D is the average thermal diffusivity, all of which are assumed to be constant. The weighted mass fraction $\bar{\phi} = [\phi + (1 - \phi)(\rho_s c_s / \rho_l c_l)]$ is defined in terms of the porosity ϕ and the specific heats and densities of the solid and liquid phases, c_s , c_l , ρ_s , and ρ_l , respectively, and is also assumed to be constant.

Since the velocity field $\mathbf{u} = (u, v, w)$ has vanishing vertical vorticity and divergence, it can be written in terms of a scalar velocity-potential function ψ that satisfies

$$\mathbf{u} = \nabla \wedge (\nabla \wedge \psi \hat{\mathbf{z}}) = \begin{pmatrix} \psi_{xz} \\ \psi_{yz} \\ -\psi_{xx} - \psi_{yy} \end{pmatrix}. \quad (2.3)$$

Given this form, Darcy’s law (2.1b) reduces to $\nabla_H [\nabla^2 \psi + (Kg\rho_0 b/\mu)T] = \mathbf{0}$, where $\nabla_H = (\partial_x, \partial_y)$ is the gradient operator in the (x, y) plane. In fact, given that the velocity is unchanged by the addition of an arbitrary function of z to the velocity potential ψ , we are free to scale the integrated form of this equation by any function of z , and can thus set

$$\nabla^2 \psi = -\frac{Kg\rho_0 b}{\mu} T. \quad (2.4)$$

Columnar convection in the vertical direction with a rectangular horizontal planform provides a steady solution to these equations, with horizontal wavevector $(k^*, \xi k^*)$ (see figure 1) and thermal amplitude \hat{A}^* :

$$T_0 = \hat{A}^* \cos(k^* x) \cos(\xi k^* y) - \frac{\mu D k^{*2} (1 + \xi^2) z}{Kg\rho_0 b}, \quad (2.5a)$$

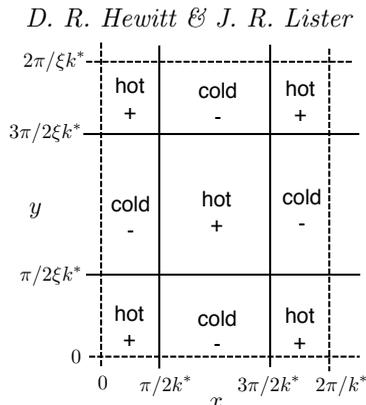

Figure 1: A schematic of the base flow (2.5) in the region $0 \leq x \leq 2\pi/k^*$ and $0 \leq y \leq 2\pi/(\xi k^*)$ in the (x, y) plane (shown here with $\xi < 1$). The pattern periodically repeats outside this range. The temperature and the sign of the vertical velocity (w) in each rectangle is marked.

$$\psi_0 = \frac{Kg\rho_0 b \widehat{A}^*}{\mu k^{*2} (1 + \xi^2)} \cos(k^* x) \cos(\xi k^* y) + \frac{Dk^{*2} (1 + \xi^2) z^3}{6}. \quad (2.5b)$$

The horizontal velocities (u_0, v_0) associated with this solution are zero, and the vertical velocity is $w_0 \propto \cos(k^* x) \cos(\xi k^* y)$. A striped planform (i.e. two-dimensional flow with wavenumber k^*) and a square planform are recovered in the limits $\xi \rightarrow 0$ and $\xi = 1$, respectively.

2.2. Nondimensionalisation

We rescale the problem using the lengthscale $1/k^*$ of the base columnar flow and a diffusive time scale to give the dimensionless variables

$$(X, Y, Z) = k^*(x, y, z); \quad \tau = \frac{k^{*2} D}{\phi} t; \quad \Psi = \frac{k^*}{D} \psi; \quad \Theta = \frac{Kg\rho_0 b}{\mu D k^*} T, \quad (2.6)$$

together with $\mathbf{U} = (U, V, W) = \mathbf{u}/(k^* D)$. The governing equations and base columnar flow become

$$\nabla^2 \Psi = -\Theta, \quad \Theta_\tau + \Psi_{XZ} \Theta_X + \Psi_{YZ} \Theta_Y - (\Psi_{XX} + \Psi_{YY}) \Theta_Z = \nabla^2 \Theta, \quad (2.7a, b)$$

$$\Theta_0 = A \cos X \cos \xi Y - (1 + \xi^2) Z, \quad (2.8a)$$

$$\Psi_0 = \frac{A}{(1 + \xi^2)} \cos X \cos \xi Y + \frac{(1 + \xi^2) Z^3}{6}, \quad (2.8b)$$

where subscripts of X , Y and τ denote partial derivatives, and the parameter

$$A = \frac{Kg\rho_0 b}{\mu D k^*} \widehat{A}^*, \quad (2.9)$$

is the rescaled and dimensionless amplitude. Note that A can also be thought of as an effective Rayleigh number for the problem, based on the length and temperature scale of the columnar flow. We note for later discussion that, if the system was instead non-dimensionalised with respect to an external temperature and length scale, as might be the case in a Rayleigh–Darcy cell of dimensional height L and temperature difference Δ , the parameter A would be related to the resultant Rayleigh number Ra for that system by

$A = \widehat{A}^* Ra/k^* L\Delta = \widehat{A} Ra/k$, where $\widehat{A} \equiv \widehat{A}^*/\Delta$ and $k \equiv Lk^*$ would be the dimensionless amplitude and wavenumber with respect to the new temperature and length scales. We return to use this relationship in the discussion of §5.

2.3. Linear stability equations

In order to assess the stability of the base flow (2.8), we introduce small perturbations $[\tilde{\Theta}, \tilde{\Psi}]$ of the form

$$\tilde{\Theta} = \text{Re} \{G(X, Y) \exp[\sigma\tau + i\alpha Z]\}, \quad \tilde{\Psi} = \text{Re} \{F(X, Y) \exp[\sigma\tau + i\alpha Z]\}, \quad (2.10a, b)$$

where $|G|, |F| \ll 1$. Perturbations grow or decay exponentially if the growth rate $\text{Re}\{\sigma\}$ is positive or negative, respectively. The perturbations satisfy the linearized set of equations

$$\alpha^2 F - F_{XX} - F_{YY} = G, \quad (2.11a)$$

$$\begin{aligned} \sigma G + i\alpha A (G \cos X \cos \xi Y - F_X \sin X \cos \xi Y - \xi F_Y \cos X \sin \xi Y) \\ + (1 + \xi^2) (F_{XX} + F_{YY}) = -\alpha^2 G + G_{XX} + G_{YY}. \end{aligned} \quad (2.11b)$$

Given the periodicity of the base flow and equations, we can look for expansions of G and F as Floquet double sums:

$$\begin{pmatrix} F \\ G \end{pmatrix} = \exp[i\beta X + i\xi\gamma Y] \sum_{n,m=-\infty}^{+\infty} \begin{pmatrix} F_{nm} \\ G_{nm} \end{pmatrix} \exp[inX + i\xi mY], \quad (2.12)$$

with leading-order horizontal (x and y) wavenumbers β and $\xi\gamma$, respectively. Furthermore, owing to the symmetries of the problem, we can restrict attention to the range $0 \leq \beta, \gamma \leq 0.5$.

After eliminating F_{nm} , the resultant perturbation equations form an infinite matrix eigenvalue problem, $M_{nmjk} G_{jk} = \sigma G_{nm}$, for a 4th-rank tensor M with coefficients

$$M_{n,m,n,m} = -\Gamma_{n,m}^2 + \frac{(1 + \xi^2) (\Gamma_{n,m}^2 - \alpha^2)}{\Gamma_{n,m}^2}, \quad (2.13a)$$

$$M_{n,m,n+1,m+1} = \frac{-iA\alpha}{4} \left\{ 1 + \left[\frac{\beta + n + 1 + \xi^2 (\gamma + m + 1)}{\Gamma_{n+1,m+1}^2} \right] \right\}, \quad (2.13b)$$

$$M_{n,m,n+1,m-1} = \frac{-iA\alpha}{4} \left\{ 1 + \left[\frac{\beta + n + 1 - \xi^2 (\gamma + m - 1)}{\Gamma_{n+1,m-1}^2} \right] \right\}, \quad (2.13c)$$

$$M_{n,m,n-1,m+1} = \frac{-iA\alpha}{4} \left\{ 1 - \left[\frac{\beta + n - 1 - \xi^2 (\gamma + m + 1)}{\Gamma_{n-1,m+1}^2} \right] \right\}, \quad (2.13d)$$

$$M_{n,m,n-1,m-1} = \frac{-iA\alpha}{4} \left\{ 1 - \left[\frac{\beta + n - 1 + \xi^2 (\gamma + m - 1)}{\Gamma_{n-1,m-1}^2} \right] \right\}, \quad (2.13e)$$

$$M_{n,m,i,j} = 0 \quad \text{otherwise}, \quad (2.13f)$$

where $\Gamma_{n,m}^2 = \alpha^2 + (\beta + n)^2 + \xi^2 (\gamma + m)^2$, and we have added commas between the tensor components for clarity. Given an eigensolution G_{nm} , the corresponding matrix F_{nm} is constructed using $F_{nm} = G_{nm}/\Gamma_{n,m}^2$ from (2.11a), and the functions F and G can be calculated via (2.12).

3. Solutions

3.1. No flow: $A = 0$

If $A = 0$, there is no columnar flow and the growth rate is

$$\sigma = \frac{(1 + \xi^2)(\beta^2 + \gamma^2)}{\alpha^2 + \beta^2 + \gamma^2} - (\alpha^2 + \beta^2 + \gamma^2). \quad (3.1)$$

This is the usual overturning instability of the linearly unstable background temperature gradient (the Rayleigh mode), and takes the form of large-scale rolls. The maximum growth rate $\text{Re}\{\sigma\} = 1 + \xi^2$ is attained in the limit of zero wavenumber $\alpha = \beta = \gamma = 0$. Equation (3.1) also gives the growth rate for $A > 0$ when we only consider the largest scale of perturbations, such that only one term from the Floquet sums in (2.12) is included.

3.2. Numerical solutions for $A > 0$

If $A > 0$ and $\alpha > 0$, then the columnar flow is coupled to the instability. We solve the eigenvalue problem numerically by first truncating the double sums in (2.12) to $-N \leq n \leq N$ and $-M \leq m \leq M$, for some positive integers N and M . We solve the resultant $N \times M$ matrix equation using an Arnoldi iteration scheme, which returns the eigenvalue $\sigma = \sigma_0(A, \alpha, \beta, \gamma; \xi, N, M)$ that has the largest real part, and the corresponding eigenmatrix G_0 . For given values of α , β , γ and ξ , we determined the cut-off integers N and M by sequentially increasing their values until the relative error in the largest growth rate $\text{Re}\{\sigma_0\}$ is below 10^{-5} . More precisely, the integers were increased in one of two ways. For moderate values of ξ , we set $M = \lfloor \lambda N \rfloor$, where $\lfloor \cdot \rfloor$ indicates the integer part and $\lambda > 1$ is a parameter, and then we sequentially increased N until the growth rate had converged. For the smallest values of ξ for which we computed solutions, we instead first solved the equivalent two-dimensional problem to determine a suitable value for $N(A, \alpha, \beta)$. We then used this value for the corresponding three-dimensional calculation, while sequentially increasing M until the growth rate had converged. As an illustrative example, the eigenvalue problem for the most unstable mode at $(A, \xi) = (2^{11}, 2^{-2})$ used $N = 16$ and $M = 22$, while that for $(A, \xi) = (2^{17}, 2^{-10})$ used $N = 35$ and $M = 130$. These values are particularly sensitive to the vertical wavenumber α of the mode: in general, both N and M increased significantly for larger values of α , which indicates that shorter modes in the vertical direction have a finer horizontal structure.

By examination of the symmetries of the original perturbation equations (2.8), we can see that, given any solution (F, G) , a new linearly independent solution can be constructed with the same eigenvalue σ by the transformation $(X, Y) \rightarrow (X + \pi, Y + \pi/\xi)$. Moreover, two further linearly independent solutions with the same growth rate can be constructed by only translating in one direction, such that $X \rightarrow X + \pi$ or $Y \rightarrow Y + \pi/\xi$; the eigenvalue for these solutions has the same real part but an imaginary part with the opposite sign to σ . As such, we anticipate four linearly independent eigenmodes with the same value of $\text{Re}\{\sigma_0\}$, between which the iteration procedure described above cannot distinguish. We will return to discuss the effect of these independent solutions in §3.3 below.

3.2.1. Recap of solutions for a two-dimensional planform: $\xi = 0$

In the limit of a striped planform ($\xi = 0$), both the base profile and the perturbations are two-dimensional. The structure of the instability in this case has been discussed in detail by Hewitt *et al.* (2013), and is briefly recapped here. The base state which consists of a columnar exchange flow along a linear background temperature gradient, is always unstable to a roll-like perturbation of the base temperature gradient (the

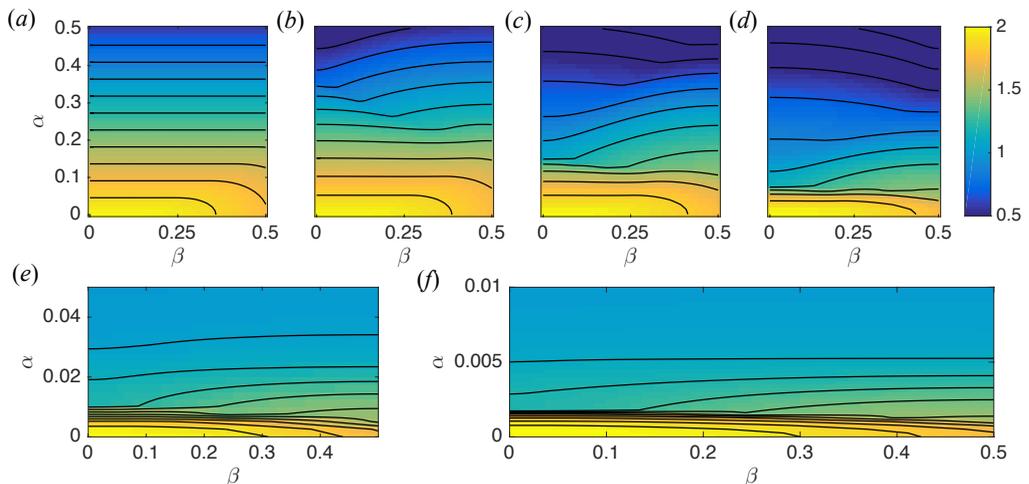

Figure 2: Density maps and contours of the maximum growth rate $\text{Re}\{\sigma_*$ maximized over γ for each value of (α, β) , for a square base planform ($\xi = 1$) and different amplitudes: (a) $A = 0$, (b) $A = 1$, (c) $A = 4$, (d) $A = 10$, (e) $A = 100$, and (f) $A = 500$. The most unstable mode always has $\alpha = \beta = \gamma = 0$.

standard Rayleigh mode). For amplitudes $A \lesssim 17.2$, this large-scale perturbation with zero wavenumber is the most unstable mode. For larger amplitudes, a new instability of the columnar flow is the most unstable, which has a dominant horizontal wavenumber $\beta = 0.5$, such that it has a periodicity double that of the base flow (often referred to as a subharmonic instability). As $A \rightarrow \infty$, the growth rate of this mode increases like $\text{Re}\{\sigma_{2D}\} \sim A^{4/9}$, while the corresponding vertical wavenumber $\alpha_{2D} \sim A^{-1/9}$ and vertical phase speed $c_{2D} = -\text{Im}\{\sigma_{2D}\}/\alpha_{2D} = \pm A$. In this limit, the ‘columnar’ mode takes the form of a claw-like positive pulse of temperature centred on an upwelling (downwelling) of the base flow, with an identical but opposite-signed pulse on the neighbouring upwelling (downwelling), resulting in propagation in the positive (negative) vertical direction, and in growth. The resultant instability of the flow develops into a ‘checkerboard’ of either pulses or depletions of the background columns.

3.2.2. Square planform: $\xi = 1$

For a given value of α and β , we denote by $\sigma_*(\alpha, \beta; \xi)$ the eigenvalue with the largest real part maximized over γ . Figure 2 shows contours of the growth rate $\text{Re}\{\sigma_*$ for a square planform of convection ($\xi = 1$), and for different values of the amplitude A . For $A = 0$, the growth rate is given by (3.1) and maximized at $\alpha = \beta = \gamma = 0$, where $\text{Re}\{\sigma_*$ = $1 + \xi^2 = 2$ (figure 2a). As A is increased, the contours bend slightly around $\beta = 0.5$, and the most significant variation in the growth rate becomes confined to an increasingly narrow region near $\alpha = 0$ (e.g. figure 2e,f). However, the mode with zero wavenumber remains the most unstable. Thus, the large-scale overturning instability of the background density gradient remains the dominant instability, irrespective of the strength of the square columnar flow, and there is no transition to a ‘columnar’ most unstable mode. This behaviour is quite different from the two-dimensional case ($\xi \rightarrow 0$) discussed above.

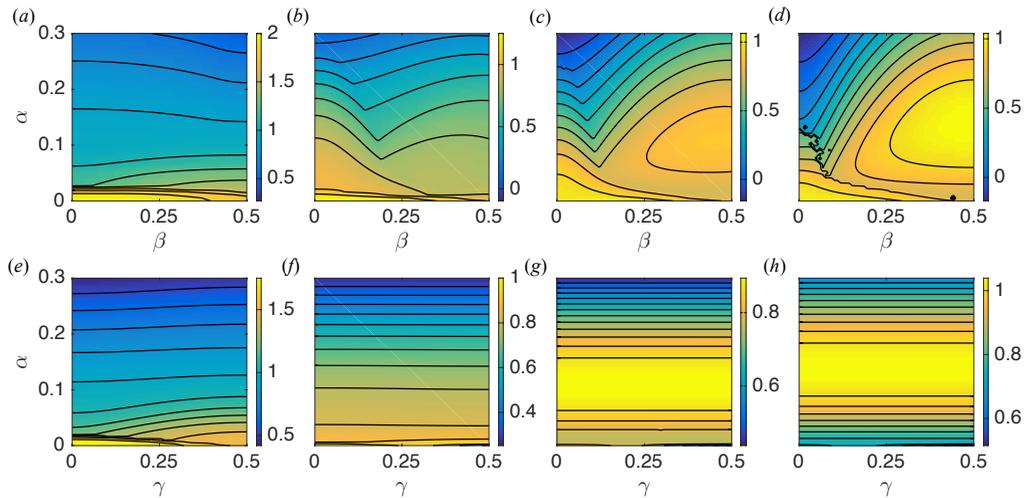

Figure 3: Density maps and contours of the maximum growth rate for $A = 32$ and different aspect ratios. (a–d) The growth rate $\text{Re}\{\sigma_*$ maximized over γ for each value of (α, β) . (e–h) The growth rate $\text{Re}\{\sigma_0\}$ for fixed $\beta = 0.5$, as a function of γ and α . The aspect ratios are (a,e) $\xi = 1$, (b,f) $\xi = 0.5$, (c,g) $\xi = 0.25$, and (d,h) $\xi = 0.125$. As ξ is decreased from $\xi = 1$, a local maximum appears at $\beta = 0.5$ and $\alpha > 0$, and the growth rate of this mode becomes independent of γ .

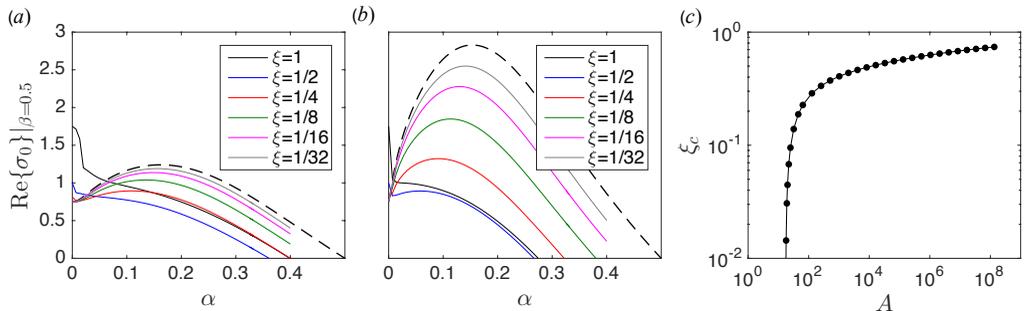

Figure 4: The maximum growth rate $\text{Re}\{\sigma_0\}$ at fixed $\beta = 0.5$ and $\gamma = 0$, for different aspect ratios ξ of the base state as marked, and: (a) $A = 2^5$; (b) $A = 2^8$. In each case, the dashed line shows the two-dimensional result (i.e. the limit $\xi \rightarrow 0$). (c) The critical aspect ratio ξ_c , below which the columnar mode is the most unstable mode.

3.2.3. Rectangular planform: $\xi < 1$

Given that the most unstable mode is coupled to the columnar flow for a two-dimensional planform, it seems likely that a similar instability will be present with a rectangular three-dimensional planform, provided the aspect ratio ξ is sufficiently small. Furthermore, since no such instability is present for a square planform, there must be a transition in the stability properties of the columnar flow as the aspect ratio of its planform is decreased from one.

Contours of the growth rate $\text{Re}\{\sigma_*$ are shown in figure 3(a–d) for various values of the aspect ratio ξ . As ξ is decreased, the growth rate grows around a point centred on $\beta = 0.5$ and $\alpha > 0$, which indicates the presence of a new mode of instability that is linked to the base columnar flow with double its periodicity in the X -direction. For sufficiently

small values of ξ , this new mode has a larger growth rate than the overturning instability of the background temperature gradient (figure 3*d*). Interestingly, as the aspect ratio is reduced the growth rate becomes essentially independent of γ , as shown in figure 3(*e-h*), which indicates that the new columnar mode is independent of the periodicity of the flow in the Y -direction.

The presence of a new mode can be seen more clearly in figure 4(*a,b*), which shows the growth rate at fixed $\beta = 0.5$ and $\gamma = 0$ as a function of the vertical wavenumber α . For square planforms with $\xi = 1$, the growth rate decreases monotonically with α from $\alpha = 0$ as discussed above, but for smaller aspect ratios there is a local maximum in $\text{Re}\{\sigma^*\}$ at $\alpha > 0$, which becomes a global maximum as ξ is decreased past some critical value ξ_c . As ξ is decreased further and the base planform becomes increasingly long in the Y -direction, the growth rate of this columnar mode increases towards the two-dimensional result.

More formally, we define the critical aspect ratio ξ_c to be the largest value of ξ such that $\text{Re}\{\sigma^*(\alpha, \beta = 0.5; \xi)\} \geq \text{Re}\{\sigma^*(0, 0; \xi)\} \equiv 1 + \xi^2$ for some $\alpha > 0$. Calculations of ξ_c extracted using a root-finding algorithm (figure 4*c*) show that ξ_c approaches one very slowly as $A \rightarrow \infty$, and that $\xi_c \rightarrow 0$ as A approaches the critical value of 17.2, below which the background overturning instability is always the most unstable mode.

We define $\sigma = \sigma_m(A, \xi)$ to be the eigenvalue with the largest real part maximized over α , β and γ , and denote the corresponding wavenumbers at which this value is attained by α_m , β_m and γ_m . The vertical phase speed corresponding to this mode is given by $c_m = -\text{Im}\{\sigma_m\}/\alpha_m$. As discussed above, for $\xi < \xi_c(A)$, $\beta_m = 0.5$ and σ_m becomes independent of γ . We therefore choose to set $\gamma_m = 0$ in all subsequent calculations.

Figure 5(*a-c*) shows how σ_m , α_m and c_m , calculated for a fixed large amplitude A , approach the corresponding two-dimensional values σ_{2D} , α_{2D} and c_{2D} , as ξ is decreased towards zero. The deviation from the two-dimensional values scales linearly with ξ for each of these measures (figure 5*d-f*), and also has a systematic dependence on the amplitude A (figure 5*g-i*). The data indicates that

$$\text{Re}\{\sigma_m\} - \text{Re}\{\sigma_{2D}\} \sim \xi A^{3/9} \text{Re}\{\sigma_{2D}\} \sim \xi A^{7/9}, \quad (3.2a)$$

$$\alpha_m - \alpha_{2D} \sim \xi A^{3/9} \alpha_{2D} \sim \xi A^{2/9}, \quad (3.2b)$$

$$c_m - c_{2D} \sim \xi A^{-1/9} c_{2D} \sim \xi A^{8/9}, \quad (3.2c)$$

as $\xi \rightarrow 0$ and for large A , given the scalings for the two-dimensional quantities reported in §3.2.1. We will derive and explain these scalings via an asymptotic analysis in the limit of small ξ in §4 below.

If, instead, we fix the aspect ratio and consider the limit $A \rightarrow \infty$, we find that the growth rate and corresponding vertical wavenumber gradually deviate from the two-dimensional values (figure 6*a-c*). Indeed, while the deviation from the two-dimensional values shows the same scalings as identified in (3.2) above (figure 6*d-f*) for relatively low amplitudes, the quantities diverge as $A \rightarrow \infty$. Results for smaller values of ξ remain closer to the two-dimensional data up to higher amplitudes, but still follow a different trend for sufficiently large values of A .

3.3. Planform of instability

The approach of the maximum growth rate towards the two-dimensional value can in part be understood by an examination of the corresponding eigenmodes. Figure 7(*a*) shows profiles in the $(X, \xi Y)$ plane of a temperature perturbation $\hat{\theta}$ that gives the maximum growth rate for a base state with a relatively large amplitude. This particular

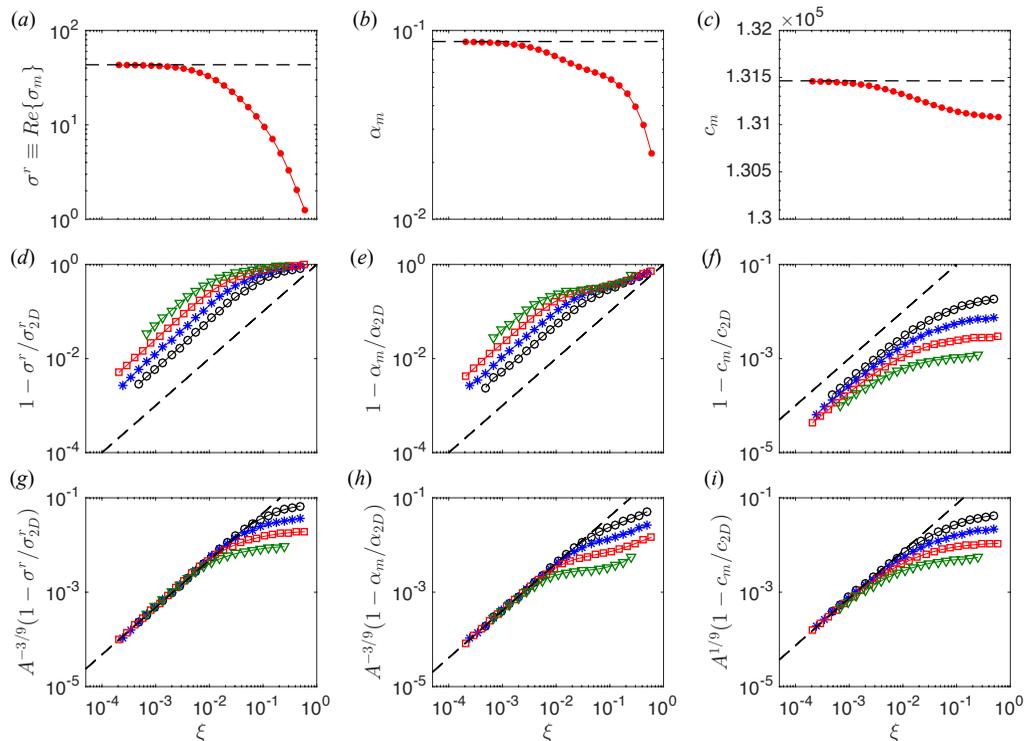

Figure 5: Data (dots) as a function of aspect ratio ξ , for different A . (*a-c*) The maximum growth rate $\sigma^r \equiv \text{Re}\{\sigma_m\}$, with the corresponding vertical wavenumber α_m and the propagation speed c_m for $A = 2^{17}$, which tends towards the corresponding values in two dimensions (black dashed) as $\xi \rightarrow 0$. (*d-f*) The scaled deviation from the two-dimensional results for the same three quantities, and for $A = 2^{11}$ (black circles), $A = 2^{14}$ (blue stars), $A = 2^{17}$ (red squares) and $A = 2^{20}$ (green triangles). The black dashed lines have unit slope. (*g-i*) The same data having been scaled by a suitable power of A as marked, together with the asymptotic predictions for $\xi \rightarrow 0$ (black dashed), taken from (4.13) (see asymptotic analysis in §4).

mode has a negative phase speed, and the corresponding background planform is shown in figure 7(c). For $\xi = \xi_c$, the mode takes the form of a weak cold pulse, centred on a cold background column in the background flow, and a neighbouring warm pulse centred on the next downwelling column in the X -direction, with only weak perturbations affecting the surrounding upwelling columns. As ξ is decreased, this pattern becomes increasingly concentrated around $\xi Y = 2n\pi$ or $\xi Y = (2n + 1)\pi$, with large regions of negligible perturbation between pulses. For very small aspect ratios, regions of near-zero perturbation cover the vast majority of the plane (figure 7a; right-hand plots): pulses decay rapidly away from the centre of the background columns and appear to become completely isolated from neighbouring pulses in the Y -direction. In addition, the temperature perturbation across a pulse in the X -direction (figure 7d) tends towards a double-peaked or claw-shaped sinusoidal profile as $\xi \rightarrow 0$, with maxima or minima located on either side of the background downwelling columns. This is the profile of the two-dimensional columnar instability.

As previously mentioned, the symmetries of the equations permit a linearly independent solution with the same eigenvalue. This solution is shown in figure 7(b), and consists

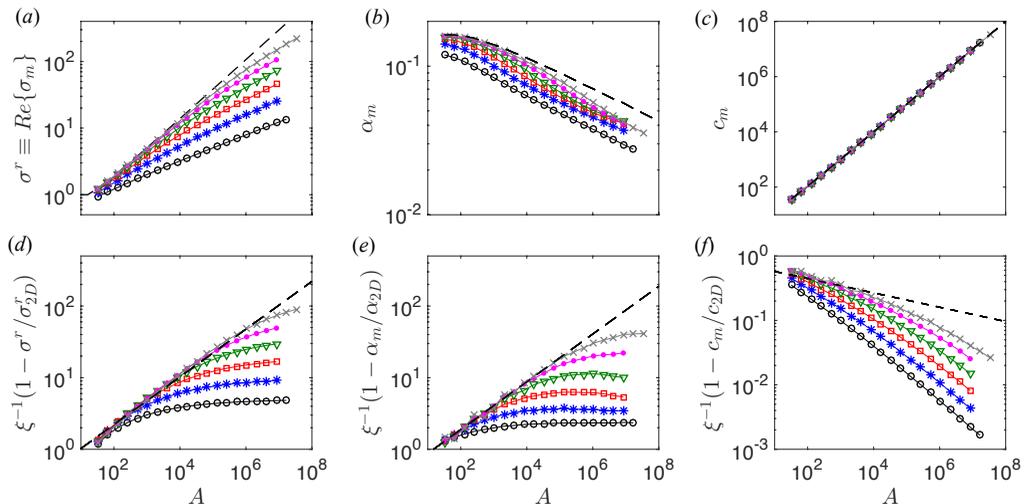

Figure 6: Data (dots) as a function of A , for different aspect ratios ξ . (*a-c*) The maximum growth rate $\sigma^r \equiv \text{Re}\{\sigma_m\}$, with the corresponding vertical wavenumber α_m and the propagation speed c_m , together with the two-dimensional results (black dashed lines), which exhibit asymptotic scalings of $\text{Re}\{\sigma_{2D}\} \sim A^{4/9}$, $\alpha_{2D} \sim A^{-1/9}$, and $c_{2D} \sim A$ as $A \rightarrow \infty$. (*d-f*) The relative deviation from the two-dimensional results, scaled by the aspect ratio ξ , for the same three quantities. Dashed lines show the asymptotic predictions for $\xi \rightarrow 0$ taken from (4.13) (see asymptotic analysis in §4). The quantities deviate from the asymptotic predictions as $A \rightarrow \infty$, as discussed in §4.3. The different symbols correspond to $\xi = 1/5$ (black circles), $\xi = 1/10$ (blue stars), $\xi = 1/20$ (red squares), $\xi = 1/40$ (green triangles), $\xi = 1/80$ (pink dots), and $\xi = 1/160$ (grey crosses).

of the same pattern of pulses translated by $(\pi, \pi/\xi)$. By taking any linear combination of these two solutions, one can construct a family of admissible eigenmodes which, for small ξ , takes the form of a ‘checkerboard’ pattern of pulses centred on every column in the Y -direction of the base profile, with an arbitrary relative magnitude between each pair of neighbouring pulses.

This observation suggests that perturbations centred on a particular column of the base flow do not interact with perturbations on the neighbouring column in the Y -direction, which, in turn, suggests that the growth rate will be independent of the periodicity of the eigenmode in the Y -direction. This suggestion is consistent with the previously observed independence of the maximum growth rate on the wavenumber γ , which dictates the periodicity in the Y -direction.

The large regions of near-zero perturbation between neighbouring pulses are the results of a strong modulation of the perturbation in the Y -direction. Figure 8(*a*) shows the decay of the perturbation away from the centre of a pulse, which takes a Gaussian-like form with a weak dependence on the amplitude A . Using such profiles, we define a decay length Y_d to be the distance in the Y -direction from the centre of a pulse to the point where the magnitude of the perturbation has fallen to 10% of its original value, averaged over X . The decay length scales with $Y_d \sim \xi^{-1/2}$ as $\xi \rightarrow 0$ (figure 8*b*), and displays a very weak dependence on A (which we identify in the asymptotic analysis of §4 as $Y_d \sim \xi^{-1/2} A^{-1/18}$). Thus, despite the apparent localization of the perturbation in ξY space, the envelope of the modulation actually grows like $\xi^{-1/2}$ as $\xi \rightarrow 0$.

Finally, we note that two complementary eigenmodes to those shown in figure 7 could

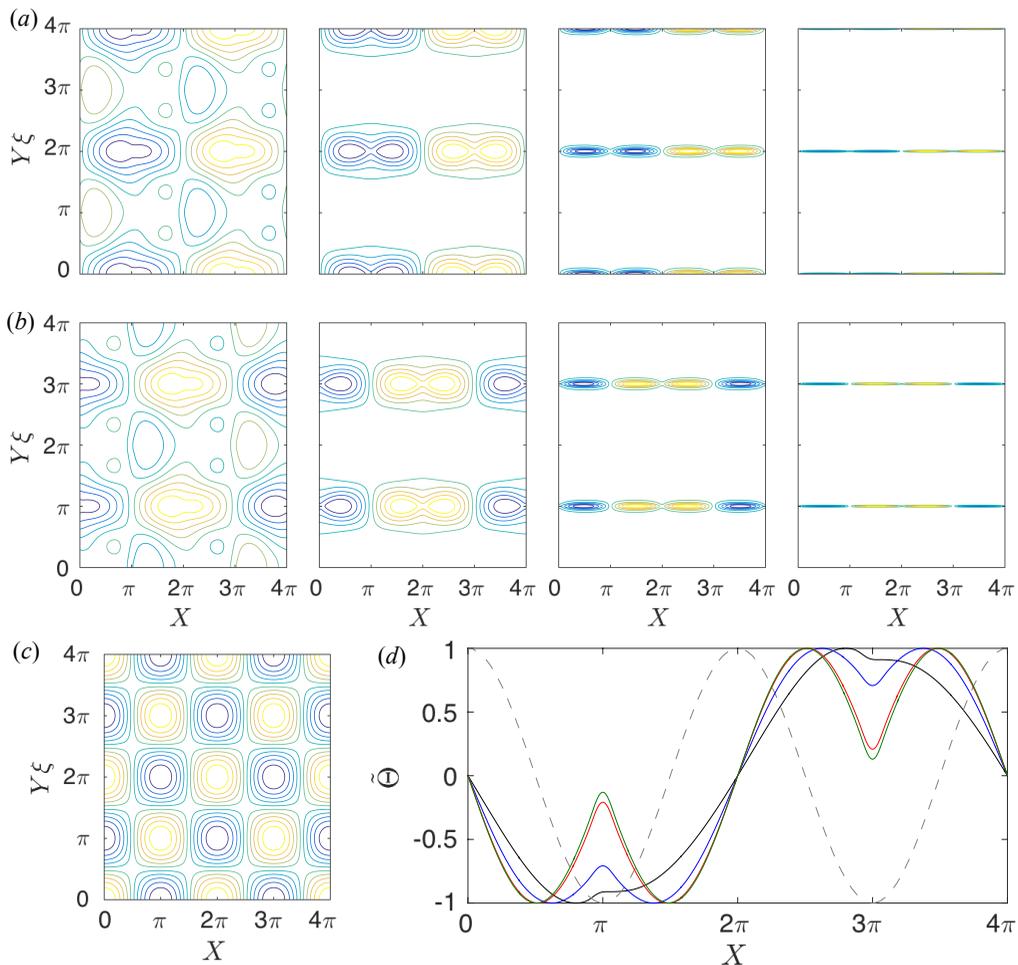

Figure 7: Eigenmodes for $A = 2^{17}$. (a) The temperature perturbation $\tilde{\Theta}$ at a fixed depth z with $\gamma = 0$, for $\xi = \xi_c = 0.573$ (far left), $\xi = 2^{-2}$ (middle left), $\xi = 2^{-6}$ (middle right), and $\xi = 2^{-10}$ (far right). The perturbations are periodic with period 4π in the X -direction and $2\pi/\xi$ in the Y -direction. (b) A set of linearly independent solutions with the same aspect ratios as in (a). The solutions in (a) and (b) have the same growth rate and the same (negative) phase speed; any linear combination of these modes is also a solution. (c) Contours of the corresponding background temperature field. (d) Temperature perturbations $\tilde{\Theta}(X, Y = 0)$ for the modes shown in (a), with $\xi = \xi_c$ (black), $\xi = 2^{-2}$ (blue), $\xi = 2^{-6}$ (red), and $\xi = 2^{-10}$ (green). The dashed line shows the corresponding background temperature profile Θ_0 at $Y = 0$ for reference.

be constructed by the translation $X \rightarrow X + \pi$; these modes would have the same growth rate but would consist of pulses centred on neighbouring upwelling, rather than downwelling, columns of the background flow, and would have a positive, rather than negative, phase speed.

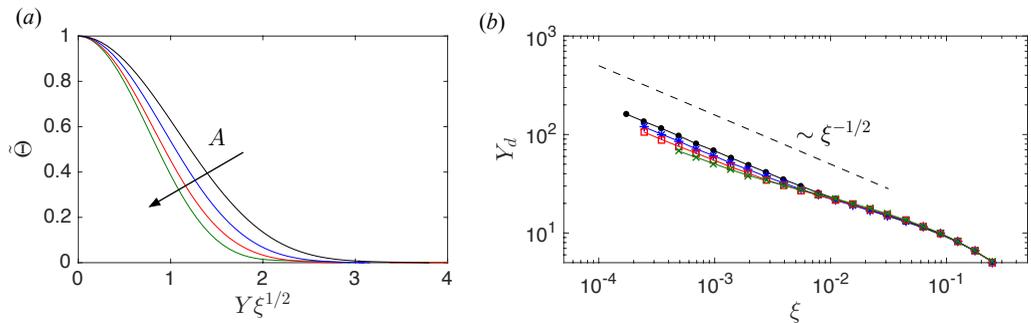

Figure 8: (a) The decay of the perturbation temperature in the Y -direction for $\xi = 2^{-11}$. The profiles here are taken along the line $X = 5\pi/2$, for modes that are aligned as in figure 7(a), for which there is a temperature maximum at $(X, Y) = (5\pi/2, 0)$ (this maximum is scaled to one here). (b) The distance Y_d over which profiles decay in the Y -direction, as defined in the main text. Colours and symbols correspond to $A = 2^{11}$ (black dots), $A = 2^{14}$ (blue star), $A = 2^{17}$ (red squares) and $A = 2^{20}$ (green crosses).

4. Asymptotic analysis in the limit $\xi \rightarrow 0$

In order to further understand how the three-dimensional instability of the columnar structure approaches the two-dimensional instability in the limit of long, thin columns, we undertake an asymptotic expansion of the linear perturbation equations in the joint limit $\xi \rightarrow 0$ and $A \rightarrow \infty$. In this section, we first give a brief review of the two-dimensional problem (see Hewitt *et al.* (2013) for more details), and then outline the scalings in three dimensions that give rise to the behaviour reported in (3.2). A detailed description of the asymptotic solution is given in Appendix A.

We consider the limit of large A and, based on the symmetries of the governing equations, restrict attention to solutions $[G, F]$ that are even under reflection about $X = 0$ and odd under reflection about $X = \pm\pi$. These solutions correspond to boundary conditions $F'(0) = G'(0) = 0$ and $F(\pi) = G(\pi) = 0$.

4.1. Two-dimensional flow

We first revisit the two-dimensional problem, for which the equations reduce to

$$G + F'' = \alpha^2 F, \quad \sigma G + i\alpha A [G \cos X - F' \sin X] + F'' = G'' - \alpha^2 G, \quad (4.1a, b)$$

where F and G are functions of X alone. The asymptotic expansion in the limit $A \rightarrow \infty$ and $\alpha \ll 1$ gives leading-order outer solutions of $G = \sin X$ and $F = \sin X - X + \pi$ in $(0, 2\pi]$, with $\sigma = -i\alpha A + \sigma^*$. These solutions cannot satisfy the boundary conditions at $X = 0$, and instead match to a thin boundary layer there. A balance between horizontal diffusion, advection and growth, together with the form of the outer solution for small X , suggests scalings

$$\tilde{x} = (\alpha A)^{1/4} X, \quad s = (\alpha A)^{-1/2} \sigma^*, \quad g = (\alpha A)^{1/4} G, \quad f = (\alpha A)^{3/4} F, \quad \alpha^* = \alpha A^{1/9}, \quad (4.2)$$

for the inner region, while (4.1) becomes

$$f'' + g = (\alpha A)^{1/4} \lim_{X \rightarrow 0} \alpha^2 F = \alpha^{*9/4} \pi, \quad \left(s - \frac{i\tilde{x}^2}{2} \right) g - i\tilde{x} f'_0 = g''. \quad (4.3a, b)$$

Equation (4.3) is solved subject to $g'(0) = f'(0) = 0$ and $f' \rightarrow -\tilde{x}^2/2 - \alpha^{*9/4} \pi \tilde{x}$ as $\tilde{x} \rightarrow \infty$. The third of these boundary conditions, which comes from matching to

the leading-order outer solution, can be shown to impose two constraints on solutions of (4.3), and thus determines the dispersion relationship $s(\alpha^*)$. Numerical solution of these equations gives a maximum for $s(\alpha^*)$ at $\alpha^* = 0.332$, such that the leading-order maximum growth rate occurs at vertical wavenumber $\alpha = 0.332A^{-1/9}$ and is $\text{Re}\{\sigma^*\} = (\alpha A)^{1/2} \text{Re}\{s(\alpha^*)\} = 0.2308A^{4/9}$

4.2. Three-dimensional flow

In three dimensions, we look for solutions in the limit $\xi \ll 1$ that resemble the two-dimensional solutions but are subject to a ‘slow’ modulation in the Y -direction (i.e. over a scale larger than the $O(1)$ variation in the X direction). As in two dimensions, we set $\sigma = -i\alpha A + \sigma^*$, with σ^* to be determined. The governing equations in the outer region are

$$G + F_{XX} = \alpha^2 F - F_{YY} \ll 1, \quad (4.4a)$$

$$(1 - \cos X \cos \xi Y) G + (\sin X \cos \xi Y) F_X = O\left((\alpha A)^{-1}\right), \quad (4.4b)$$

which have the leading-order solution

$$F = a(Y) [\sin X \cos \xi Y - X + \pi], \quad G = a(Y) \sin X \cos \xi Y, \quad (4.5)$$

for some modulating amplitude $a(Y)$ to be determined. We again expect an inner region near $X = 0$, where

$$G + F'' = \lim_{X \rightarrow 0} \{\alpha^2 F - F_{YY}\} = \pi(\alpha^2 a - a_{YY}), \quad (4.6a)$$

$$\sigma^* G - i\alpha A \left[\left(\frac{X^2}{2} + \frac{\xi^2 Y^2}{2} \right) G + iX F_X \right] = G_{XX} + O(F\xi^2 Y^2, F_{XX}). \quad (4.6b)$$

A balance of the terms that are independent of ξ in (4.6) gives the two-dimensional scalings for the inner region, as in (4.2). A further balance of the relative magnitude of the first-order correction terms in (4.6a) and (4.6b) gives $a_{YY}/(a\alpha^2) \sim \xi^2 Y^2/X^2$, or $Y \sim (\xi^4 \alpha^5 A)^{-1/8} \sim \xi^{-1/2} A^{-1/18}$, given $X \sim (\alpha A)^{-1/4}$ as in (4.2). The relative size δ of each of these correction terms is $\delta \sim \xi(\alpha^{-3} A)^{1/4} \sim \xi A^{3/9}$.

We therefore introduce a stretched coordinate in the Y -direction,

$$\tilde{y} = (\xi^4 \alpha^5 A)^{1/8} Y = \alpha^{5/8} \xi^{1/2} A^{1/18} Y, \quad (4.7)$$

together with scalings for the inner region,

$$\tilde{x} = (\alpha A)^{1/4} X, \quad s = (\alpha A)^{-1/2} \sigma^*,$$

$$g = (\alpha A)^{1/4} G/a(Y), \quad f = (\alpha A)^{3/4} F/a(Y), \quad \alpha^* = \alpha A^{1/9}, \quad (4.8)$$

and the scale

$$\delta \equiv \xi(\alpha^{-3} A)^{1/4} \equiv \alpha^{*-3/4} \xi A^{3/9}, \quad (4.9)$$

at which we expect a correction to the leading-order two-dimensional solutions.

The equations in the inner region near $X = 0$ become

$$g + f'' = \pi\eta, \quad (4.10a)$$

$$\left(\Sigma - \frac{i\tilde{x}^2}{2} \right) g - i\tilde{x} f' = g'', \quad (4.10b)$$

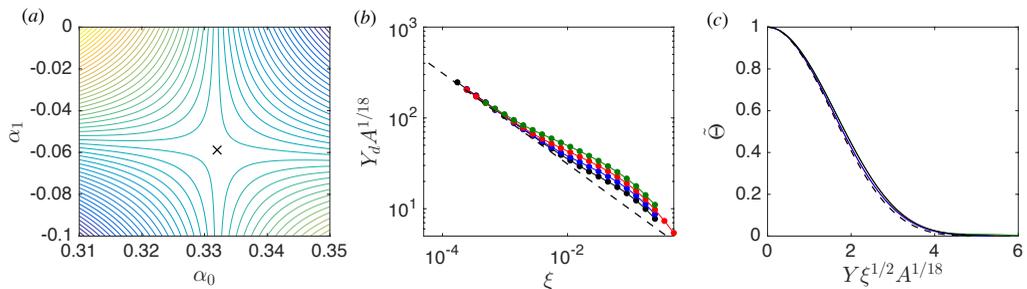

Figure 9: (a) Contours of the correction to the growth rate $\text{Re}\{S_1\}$ as a function of the wavenumbers α_0 and α_1 , as defined in the Appendix. The saddle point $(\alpha_0, \alpha_1) = (0.332, -0.059)$ is marked by a cross. (b) The width Y_d of the profiles in the y -direction, as defined in figure 8(b), scaled by $A^{-1/18}$, and compared with the predicted width from the asymptotic analysis (4.12) (dashed line). (c) Temperature profiles in the Y -direction for $\xi = 2^{-11}$, as in figure 8(b), scaled by $A^{-1/18}$ and compared with the Gaussian asymptotic prediction in (4.12) (dashed). In (b) and (c), colours correspond to $A = 2^{11}$ (black), $A = 2^{14}$ (blue), $A = 2^{17}$ (red) and $A = 2^{20}$ (green).

with boundary conditions $g'(0) = f'(0) = 0$ and $f' \rightarrow -\tilde{x}^2/2 - \pi\eta\tilde{x}$ as $\tilde{x} \rightarrow \infty$, where

$$\eta = \alpha^{*9/4} \left(1 - \frac{\delta a_{\tilde{y}\tilde{y}}}{a} \right), \quad \text{and} \quad \Sigma = s - \frac{\delta i \tilde{y}^2}{2}. \quad (4.11a, b)$$

Equations (4.10) are identical in form to the eigenvalue problem in two dimensions (4.3), and so the eigenvalue dispersion relationship $\Sigma(\eta)$ that results from solving (4.10) is precisely the relationship $s(\alpha^*)$ that we found previously, continued into the complex plane. In particular, since \tilde{y} is just a parameter in (4.10), we can expand η and Σ in powers of δ about their two-dimensional values, to deduce both the size of the corrections to the growth rate, phase speed and vertical wavenumber, and the structure of the modulation function $a(Y)$.

The details of this calculation are described in Appendix A. The balance at $O(\delta)$ gives predictions for the correction $S_1(\alpha_0, \alpha_1)$ to the eigenvalue σ^* , where $\alpha^* = \alpha_0 + \delta\alpha_1 + O(\delta^2)$. The most unstable mode occurs at a saddle point of $\text{Re}\{S_1\}$ (figure 9a), as discussed in Appendix A. The balance at $O(\delta)$ also provides, as a solvability condition, an ODE for the modulation function a , with a Gaussian solution $a = \exp(-d\tilde{y}^2/2)$ for a certain complex constant d .

4.3. Summary of asymptotic analysis

The resulting leading-order temperature G and horizontal velocity $\partial F/\partial X$ perturbations of the most unstable mode, away from the thin boundary layer around $X = 0$, are

$$G = \exp\left(-\hat{d}\xi A^{1/9} Y^2/2\right) \sin X \cos \xi Y, \quad (4.12a)$$

$$\frac{\partial F}{\partial X} = \exp\left(-\hat{d}\xi A^{1/9} Y^2/2\right) [\cos X \cos \xi Y - 1], \quad (4.12b)$$

with

$$\alpha = \alpha_0 A^{-1/9} + \hat{\alpha}_1 \xi A^{2/9} + \dots \quad (4.13a)$$

$$\text{Re}\{\sigma\} = \hat{S}_0 A^{4/9} + \hat{S}_1 \xi A^{7/9} + \dots \quad (4.13b)$$

$$c = A + c_1 \xi A^{8/9} + \dots \quad (4.13c)$$

where

$$\hat{d} = \alpha_0^{5/4} d = 0.43 - 0.134i; \quad \alpha_0 = 0.332; \quad \hat{\alpha}_1 = \alpha_0^{-3/4} \alpha_1 = -0.135; \quad (4.14)$$

$$\hat{S}_0 = \text{Re}\{S_0\} = 0.2308; \quad \hat{S}_1 = \alpha_0^{-3/4} \text{Re}\{S_1\} = -0.1099; \quad (4.15)$$

$$c_1 = \alpha_0^{-5/4} \text{Im} \left\{ S_1 - \frac{\alpha_1 S_0}{2\alpha_0} \right\} = -0.743. \quad (4.16)$$

The profiles are modulated in the Y -direction like a Gaussian wavepacket which decays over a length $Y_d \sim \xi^{-1/2} A^{-1/18}$. In fact, since $\text{Re}\{\hat{d}\} > \text{Im}\{\hat{d}\}$, the period of the oscillation is greater than Y_d , and the profile is dominated by the Gaussian decay. The asymptotic prediction of Y_d gives excellent agreement with the numerical results of the Floquet analysis (figure 9*b*), as does the predicted Gaussian envelope (figure 9*c*). The correction terms for the growth rate, wavenumber and phase speed also all give very good agreement with the numerical results (see the dashed lines in figure 5*g-i* and figure 6*d-f*). Given that this asymptotic analysis relies on an expansion in powers of $\delta \sim \xi A^{1/3}$, it is evident that the expansions will break down if $A \gtrsim \xi^{-3}$, as can be observed in the numerical solutions shown in figure 6(*d-f*).

4.4. *Physical mechanism of modulation*

In two dimensions, the most unstable mode propagates with the maximum speed $|c| = A$ of the background flow (Hewitt *et al.* 2013). Away from the thin boundary layers, it constitutes a neutral balance between horizontal advection of the base temperature field and vertical advection of the resultant thermal perturbation by the base flow. The mode grows exponentially in time because of the influence of horizontal diffusion in the thin boundary layers between neighbouring cells, which introduces an imbalance in the vertical phase of the perturbation.

We have found that the most unstable mode for long, thin, columnar exchange flow in three dimensions takes the same leading-order form, but is modulated in the Y -direction. In order to briefly discuss the physical basis for the modulation, we consider a perturbation centred on $Y = 0$. Outside the boundary layers, the Y -dependence of the perturbation induces weak variations in the vertical velocity ($\sim \Psi_{XX} + \Psi_{YY} \sim F_{XX} + F_{YY}$) and vertical pressure gradients ($\sim \Psi_{ZZ} \sim \alpha^2 F$) away from $Y = 0$. While these variations have no effect on the leading-order neutral interior balance discussed above, they do provide a perturbation to the temperature in the boundary-layer regions (through the right-hand side of (4.6*a*)). The Y -dependence of the background flow does not itself affect the dominant balances in the outer region at all.

Within the boundary layers, however, the locally quadratic variation of the background profile in the Y -direction weakens the base vertical velocity away from $Y = 0$, and so reduces the vertical transport of the perturbation temperature field (as demonstrated by the term proportional to Y^2 on the left-hand side of (4.6*b*)). As such, the temperature profile at the edge of the boundary layer is modulated in the Y -direction, which balances the perturbations from the outer region in such a way as to impose the Gaussian form of the envelope $a(Y)$. Weaker vertical advection in the boundary layer also adjusts the vertical phase of the temperature perturbation, which is the basis for the correction to the growth rate of the mode at $O(\delta)$.

5. Relevance for the spatial scales of high-Rayleigh-number convection

High- Ra convection in a three-dimensional Rayleigh–Darcy cell is dominated by vertical columnar exchange flow in the interior, driven by the growth and merging of high-wavenumber time-dependent protoplumes at the upper and lower boundaries. The interior flow has a dominant cross-sectionally averaged wavenumber $k(Ra)$, and is fairly well described by a simple steady heat-exchanger model as in (2.5). One of the motivations of this work was to explore whether the stability of unbounded heat-exchanger flow has any implications for the observed wavenumber k in a three-dimensional Rayleigh–Darcy cell.

We first observe that there is a simple upper bound for the scaling of $k(Ra)$, given the heat-exchanger framework, which is provided by a balance between $O(1)$ vertical advection along a background temperature gradient and $O(k^2/Ra)$ horizontal diffusion between columns. Such a balance gives a bound of $k \sim Ra^{1/2}$: if the exponent were any larger, vertical advection would not be strong enough to transport heat across the domain and the heat flux would vanish asymptotically.

5.1. The situation in two dimensions

In two dimensions, the flow appears to adopt a weaker scaling than the $Ra^{1/2}$ bound, with numerical data over the range $1300 \lesssim Ra \leq 4 \times 10^4$ suggesting a scaling of approximately $k \sim Ra^{0.4}$ (Hewitt *et al.* 2012). Despite the statistical scatter in this data, compensated plots of k/Ra^λ for different trial exponents λ confirm that the trend in the data is distinctly weaker than $Ra^{1/2}$ (see Hewitt *et al.* 2013). As discussed in the introduction, more recent numerical results (Wen *et al.* 2015) over a larger range of Ra reveal significant scatter in the data of $k(Ra)$ at higher values of Ra , and indicate that caution is required when averaging the wavenumber for these higher values.

Hewitt *et al.* (2013) suggested that the wavenumber adopts a weaker scaling than $k \sim Ra^{1/2}$ because of a two-dimensional version of the columnar instability mechanism that we have discussed in this paper. Specifically, they identified a simple scaling balance between the asymptotic growth rate $\text{Re}\{\sigma_{2D}\}$ of the most unstable mode and the timescale for propagation of the instability across the domain, which suggested that the flow in a Rayleigh–Darcy cell would be unstable to a columnar instability if $k > O(Ra^{5/14})$. According to this simple argument, the flow in a Rayleigh–Darcy cell is forced at the boundaries by high-wavenumber protoplumes, but coarsens due to instabilities of the columnar exchange flow until the wavenumber reaches this scaling. The argument relies on two key assumptions. First, away from the upper and lower boundaries, the interior flow behaves like an unbounded heat-exchange flow. Second, at the upper and lower boundaries, the perturbations to the interior flow associated with protoplume merging and mixing provide sufficient noise to remove any slowly growing perturbations that arrive on incoming columns, and to seed a broad spectrum on outgoing columns.

Wen *et al.* (2015) approached the problem from a different direction, by noting that the formulation in an unbounded domain may have limited applicability to a finite domain where the boundaries play such a dominant role in the dynamics. They instead found exact steady solutions to the governing equations in a finite domain, which had a qualitatively similar structure to the fully time-dependent flow, comprising thin thermal boundary layers and an interior columnar exchange flow. They studied the stability of this base state in detail, and identified two types of instability, characterized by ‘bulk’ or ‘wall’ modes, with the latter strongly localised to the upper and lower boundaries. They found that, in general, the wall modes had a significantly larger growth rate than

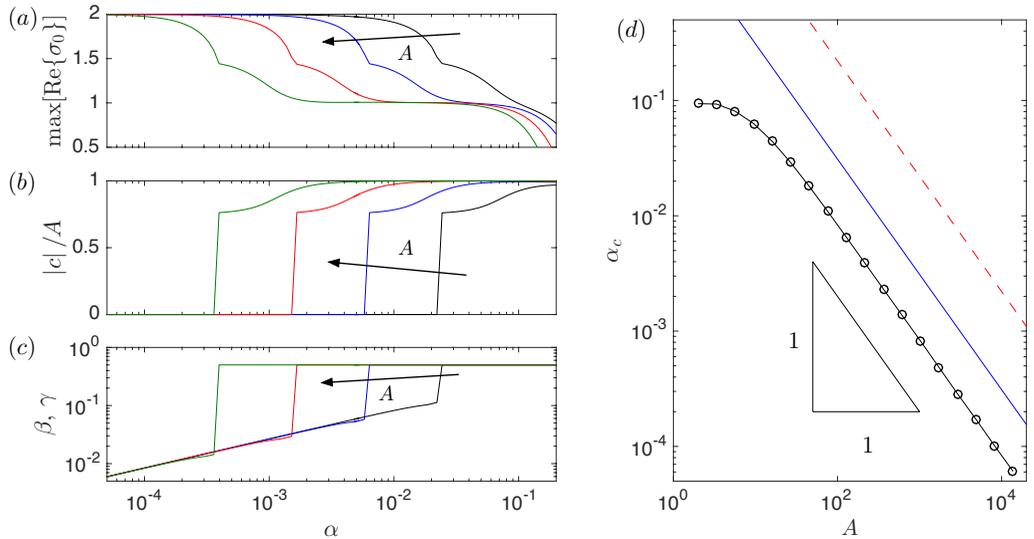

Figure 10: (a) The growth rate of the most unstable mode maximised over β and γ , as a function of α for A spaced logarithmically between $A = 32$ and $A = 2048$. (b) The corresponding phase speed, scaled by A , and (c) the corresponding horizontal wavenumbers β and γ , which increase like $\alpha^{1/2}$ before jumping to $\beta = \gamma = 1/2$. (d) The largest vertical wavenumber α_c below which the phase speed is zero (black circles), together with the minimum wavenumber α_{min} that would fit in the domain given the data for $k(Ra)$ from the simulations of Hewitt *et al.* (2014) (red dashed) or the predicted scaling of $k(Ra)$ in (5.1) (blue solid). In either case, the most unstable mode with $\alpha \gtrsim \alpha_{min}$ is a columnar mode with $\beta = \gamma = 0.5$ and growth rate $\text{Re}\{\sigma\} \rightarrow 1$ as $A \rightarrow \infty$.

the bulk modes, unless the columnar wavelength of the base state was very short. They further argued that the nonlinear evolution towards fully developed statistically steady flow resulted, in general, from an interplay of these two modes: the wall mode drives apart wide columns by the growth of small plumes from the boundaries and the bulk mode drives coarsening of narrow columns. In fact, while the great advantage of this approach is to include explicitly the upper and lower boundaries of the domain, the essence of the argument is broadly consistent with the view of Hewitt *et al.* (2013), in which the growth of protoplumes from the boundary drive apart wide columns, while narrow columns coarsen via a columnar instability.

5.2. The situation in three dimensions

Data from direct numerical simulations of convection in a three-dimensional Rayleigh–Darcy cell give an average wavenumber $k \approx 0.17Ra^{0.52 \pm 0.05}$ over a range $1750 \leq Ra \leq 2 \times 10^4$ (Hewitt *et al.* 2014; also shown in figure 11). It is important to reiterate the limitations of this data: the computations are numerically intensive, and so the data is both fairly sparse and possibly affected by restriction from the size of the domain, as discussed by Hewitt *et al.* (2014). Nevertheless, the data appears to show a scaling that is systematically stronger than that in two dimensions.

One aim of this study was to undertake a similar stability argument here to that of Hewitt *et al.* (2013), by using the stability of unbounded heat-exchanger flow with a square planform to predict the wavenumber in the bounded three-dimensional cell. In

order to make use of the results for an unbounded domain, it is evidently necessary that perturbations have a vertical scale that is much smaller than the height of the finite domain. In other words, since a Rayleigh–Darcy cell of (dimensional) depth L has dimensionless depth $Lk^* \equiv k$, where k is the wavenumber of the background flow non-dimensionalised by the depth of the domain (see scalings in §2.2), the vertical wavenumber α of any unstable mode must satisfy $\alpha \gg \alpha_{min} \equiv \pi/k$. Here $k = k(Ra)$, where $Ra = Ak/\hat{A}$ is the usual Rayleigh number and \hat{A} is the dimensionless amplitude of the base columnar flow (see §2.2). Thus, if $k \sim Ra^n$ in the Rayleigh–Darcy cell, then $\alpha_{min} \sim A^{-n/(1-n)}$. In particular, if $n = 1/2$ then $\alpha_{min} \sim A^{-1}$, while smaller values of n give a weaker decay for $\alpha_{min}(A)$.

We have already found that the most unstable mode with a square planform in an unbounded domain is simply the usual Rayleigh mode of the background linear temperature gradient, with growth rate $\text{Re}\{\sigma\} = 2$, zero phase speed and wavenumber $\alpha = 0$. This mode evidently cannot be contained in a finite cell, and so we must instead examine the most unstable mode that satisfies the constraint $\alpha > \alpha_{min}$. Contour plots of the growth rate (e.g. figure 2) show that a region of relatively large growth rate becomes increasingly localised about $\alpha = 0$ as A is increased. This behaviour is more clearly revealed in figure 10(a–c), which shows the maximum growth rate and the corresponding phase speed and horizontal wavenumbers as functions of the vertical wavenumber α . As α is increased from zero, the growth rate decreases slightly and the horizontal wavenumbers increase like $\alpha^{1/2}$ (in fact, they satisfy $\beta^2 + \gamma^2 \sim \sqrt{2}\alpha$, as can be predicted by maximising the growth rate in (3.1) for $\alpha > 0$). The phase speed $|c|$ initially remains zero. However, at some critical $\alpha = \alpha_c(A)$ there is a change in this behaviour: the maximising wavenumbers jump to $\beta = \gamma = 0.5$, the phase speed jumps up to $|c| = O(A)$, and there is a discontinuity in the slope of the growth rate. We denote modes with $\alpha < \alpha_c$ as large-scale Rayleigh-like modes, which have small horizontal wavenumber and zero phase speed, and those with $\alpha > \alpha_c$ as columnar modes, which propagate and have double the wavelength of the background columnar flow. For $\alpha > \alpha_c$, the growth rate drops towards a plateau with $\text{Re}\{\sigma\} \approx 1$ and $|c| \approx A$ (figure 10a,b).

The critical wavenumber $\alpha_c(A)$ decreases like A^{-1} (figure 10d), as can be understood by observing that the correction terms to the Rayleigh mode for $\alpha \ll 1$ in (2.13) scale with $O(\alpha A)$. According to the data for $k(Ra)$ from the direct numerical simulations of Hewitt *et al.* (2014), the smallest wavenumber $\alpha_{min} \equiv \pi/k$ that could be contained within the domain similarly decreases like A^{-1} , but is an order of magnitude larger than α_c (figure 10d). Thus, as in two dimensions, the most unstable mode that can be contained within the cell is a columnar mode, with phase speed $|c| \approx A$, but, unlike in two dimensions, it has growth rate $\text{Re}\{\sigma\} \approx 1$. A repeat of the argument presented by Hewitt *et al.* (2013) suggests that the base flow could be unstable if the timescale for propagation across the domain is greater than the timescale for growth of the instability, such that $k/A > 1/\text{Re}\{\sigma\} \gtrsim 1$. Given that $Ra = Ak/\hat{A}$ (see §2.2), this balance gives instability when

$$k \gtrsim \left(\frac{\hat{A}Ra}{\text{Re}\{\sigma\}} \right)^{1/2} \gtrsim 0.4Ra^{1/2}, \quad (5.1)$$

given $\hat{A} \approx 0.2$ (Hewitt *et al.* 2014). This is the same scaling as the upper bound identified above, and is a stronger scaling than the equivalent prediction of $k \sim Ra^{5/14}$ in two dimensions. It is also consistent with the data from direct numerical simulations, for which $k \sim Ra^{0.52 \pm 0.05}$, as can be seen in figure 11.

The result of this argument is thus consistent with the hypothesis that the wavenum-

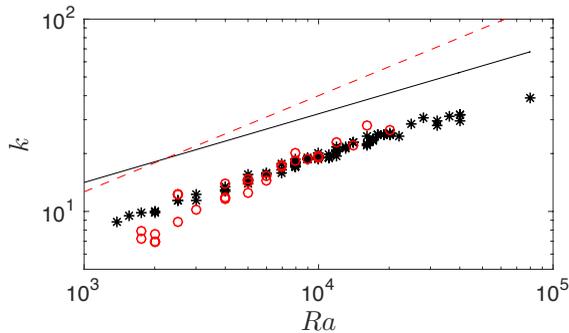

Figure 11: The predicted wavenumber from (5.1) (red dashed), together with data from direct numerical simulations (red circles) of three-dimensional convection (Hewitt *et al.* 2014). The corresponding prediction and results for two-dimensional convection, taken from Hewitt *et al.* (2013), are shown for comparison (black line and stars).

ber of the interior columnar flow in two-dimensional and three-dimensional high- Ra convection in porous media adopts different scalings because of the different stability properties of the columnar flow. Under this hypothesis, the interior flow is always forced at the boundaries by vigorous mixing of protoplumes (which have a wavenumber $\sim Ra$), and must coarsen to at least a wavenumber of $k \sim Ra^{1/2}$ in order to transport sufficient heat across the domain. In two dimensions, the interior flow is unstable to a columnar instability that drives coarsening of the columns down beyond this bound to an asymptotic wavenumber $k \sim Ra^{5/14}$. In three dimensions, the corresponding instability is weaker, and drives coarsening only to an asymptotic wavenumber $k \sim Ra^{1/2}$. In other words, the instability saturates the upper bound in three dimensions.

6. Summary

In this paper we have studied the stability of convective columnar exchange flow in an infinite three-dimensional porous medium. The flow, which consists of a rectangular sinusoidal planform of interleaving hot and cold columns with aspect ratio $\xi \leq 1$ on a linear background temperature profile, is always unstable to a large-scale overturning of the background gradient with maximum growth rate $1 + \xi^2$. Unlike in two dimensions, for a square planform ($\xi = 1$) this mode remains the most unstable irrespective of the amplitude A of the convective flow. However, flow with a rectangular planform ($\xi < 1$) can become more unstable to a perturbation of the columnar flow, with double the periodicity of the base flow, which has a growth rate that increases with A . This mode becomes the most unstable below a critical aspect ratio $\xi_c(A)$, and, in the limit $\xi \rightarrow 0$, the growth rate of this mode approaches the two-dimensional value $\text{Re}\{\sigma_{2D}\} \sim A^{4/9}$. By means of an asymptotic expansion in the joint limit $A \rightarrow \infty$ and $\xi \rightarrow 0$, we found the manner in which the growth rate, phase speed and corresponding vertical wavenumber approach their two-dimensional counterparts, and found that the flow is modulated in the long (Y) direction by a Gaussian profile that decays over a distance $\sim A^{-1/18}\xi^{-1/2}$.

Following the approach of Hewitt *et al.* (2013), we considered the relevance of these results for the spatial scales of convection in a three-dimensional Rayleigh–Darcy cell. Such an approach gives rise to a hypothesized scaling of $k \sim Ra^{1/2}$ for the average horizontal wavenumber of the interior flow in the cell, which is a stronger scaling than in two dimensions and is consistent with data from numerical simulations.

We are grateful to an anonymous referee for numerous helpful comments on an earlier draft of this manuscript.

Appendix A. Details of the asymptotic solution

In §4, we outlined the outer solution and relevant scalings for the structure of the instability in the limit $A \rightarrow \infty$ and $\xi \rightarrow 0$. The governing equations for the inner region, quoted in (4.10), provide an eigenvalue problem for $\Sigma(\eta)$, where $\Sigma = s - \delta i \tilde{y}^2/2$, $\eta = \alpha^{*9/4} (1 - \delta a_{\tilde{y}\tilde{y}}/a)$, $s = (\alpha A)^{-1/2} \sigma^*$ and $\alpha^* = \alpha A^{1/9}$. The goal of the analysis is to determine the corrections to the growth rate $\text{Re}\{\sigma^*\}$ and wavenumber α^* for non-zero aspect ratio ξ , which we expect to enter at $O(\delta)$, where $\delta = \alpha^{*-3/4} \xi A^{3/9}$ (see §4.2 for the origin of these scalings).

For ease of notation, we first introduce the scaled eigenvalue $S \equiv \sigma^*/A^{4/9} \equiv \alpha^{*1/2} s$, which satisfies

$$S = \alpha^{*1/2} s = \alpha^{*1/2} \left[\Sigma(\eta) + \frac{\delta i \tilde{y}^2}{2} \right]. \quad (\text{A } 1)$$

We then expand S and α^* to give

$$\alpha^* = \alpha_0 + \delta \alpha_1 + \dots, \quad S = S_0 + \delta S_1 + \dots \quad (\text{A } 2a, b)$$

and equate powers of δ in (A 1) to obtain

$$S_0 = \alpha_0^{1/2} \Sigma(\alpha_0^{9/4}); \quad S_1 = \alpha_1 \frac{\partial S_0}{\partial \alpha_0} + \alpha_0^{1/2} \left[\frac{i \tilde{y}^2}{2} - \frac{a_{\tilde{y}\tilde{y}}}{a} \Lambda \right], \quad (\text{A } 3a, b)$$

where we have introduced the notation $\Lambda = \alpha_0^{9/4} \Sigma'(\alpha_0^{9/4})$, and $\Sigma' = \partial \Sigma / \partial \eta$. Equation (A 3a) is simply the two-dimensional dispersion relationship. Equation (A 3b), together with the boundary conditions $a(0) = 1$, $a'(0) = 0$, and a bounded as $\tilde{y} \rightarrow \infty$, provides an ODE for the modulation function a and an eigenvalue problem for the dispersion relationship $S_1(\alpha_0, \alpha_1)$. The solution of (A 3b) is a Gaussian wavepacket,

$$a(\tilde{y}) = \exp(-d \tilde{y}^2/2); \quad d = \sqrt{\frac{i}{2\Lambda}}, \quad (\text{A } 4)$$

with eigenvalue

$$S_1 = \alpha_1 \frac{\partial S_0}{\partial \alpha_0} + d \alpha_0^{1/2} \Lambda. \quad (\text{A } 5)$$

The maximum growth rate is obtained when $\text{Re}\{\partial S / \partial \alpha\} = 0$, which, after expanding in powers of δ , occurs when

$$\frac{\partial S_0}{\partial \alpha_0} = i R_0, \quad \frac{\partial S_1}{\partial \alpha_0} = i R_1, \quad (\text{A } 6a, b)$$

for real constants R_0, R_1 . These two conditions determine the values of α_0 and α_1 , respectively, at which the growth rate is maximum.

We compute Σ' and calculate the constant R_0 by taking the derivative of (4.10) with respect to η , which gives a new eigenvalue problem for $\Sigma'(\eta)$. The first constraint (A 6a) gives $\alpha_0 = 0.332$, as in two dimensions, together with $R_0 = -0.0233$, $\Sigma'(\alpha_0^{9/4}) = -1.06 + 1.54i$, and $d = 1.708 - 0.534i$, while the second constraint (A 6b) gives $\alpha_1 = -0.059$. The resultant eigenvalue pair at this wavenumber pair is $(S_0, S_1) = (0.2308 - 0.182i, -0.0481 + 0.14i)$.

Note that the first term on the right-hand side of (A 5) is purely imaginary when the growth rate is maximized (from (A 6a)), and so the correction to the growth rate

$\text{Re}\{S_1\}$ is independent of α_1 . As a consequence, $\text{Re}\{S_1(\alpha_0, \alpha_1)\}$ is actually a stationary point in both the α_0 and α_1 directions, and, since S_1 varies linearly with α_1 , it must be a saddle point. Numerical computation of $\text{Re}\{S_1(\alpha_0, \alpha_1)\}$ confirms this prediction (figure 9a). This feature of the solutions arises because the corrections at $O(\delta)$ satisfy the same eigenvalue relationship $\Sigma(\eta)$ as at leading order. As a result, the correction to the wavenumber can only affect the phase speed of the perturbation, since it is a real perturbation to a dispersion relationship that is already maximized over the real axis. Correction to the growth rate instead requires a perturbation of η into the complex plane, which is provided by the modulation function $a(Y)$, via the parameter d in (A 5). Note that this correction is negative: the growth rate is slightly damped by the slow variation of the base state in the Y -direction.
