Abstract

Respiratory complex I (NADH:ubiquinone oxidoreductase), one of the largest membrane-bound enzymes in mammalian cells, powers ATP synthesis by using the energy from electron transfer from NADH to ubiquinone-10 to drive protons across the energy-transducing mitochondrial inner membrane. Ubiquinone-10 is extremely hydrophobic, but in complex I the binding site for its redox-active quinone headgroup is ~20 Å above the membrane surface. Structural data suggest it accesses the site by a narrow channel long enough to accommodate almost all its ~50 Å isoprenoid chain. However, how ubiquinone/ol exchange occurs on catalytically-relevant timescales, and whether binding/dissociation events are involved in coupling electron transfer to proton translocation, are unknown. Here, we use proteoliposomes containing complex I, together with a quinol oxidase, to determine the kinetics of complex I catalysis with ubiquinones of varying isoprenoid chain length, from 1 to 10 units. We interpret our results using structural data, which show the hydrophobic channel is interrupted by a highly-charged region at isoprenoids 4 to 7. We demonstrate that ubiquinol-10 dissociation is not rate determining, and deduce that ubiquinone-10 has both the highest binding affinity and the fastest binding rate. We propose that the charged region and chain directionality assist product dissociation, and that isoprenoid stepping ensures short transit times. These properties of the channel do not benefit the exhange of short-chain quinones, for which product dissociation may become rate limiting. Thus, we discuss how the long channel does not hinder catalysis under physiological conditions, and the possible roles of ubiquinone/ubiquinol binding/dissociation in energy conversion.

Significance statement

Respiratory complex I, a redox-coupled proton pumping enzyme, is central to aerobic metabolism in mammalian mitochondria, and implicated in many neuromuscular disorders. One of its substrates, ubiquinone-10, binds in an unusually long and narrow channel, which is at the intersection of the enzyme's electron and proton transfer modules and a hotspot for disease-causing mutations. Here, we use a minimal, self-assembled respiratory chain to study complex I catalyzing with ubiquinones of different isoprenoid chain lengths. We show that the channel enhances the affinity of long-chain quinones, assists in their transfer along the channel, and organizes them for product release. Finally, we discuss how efficient binding and dissociation processes may help to link redox catalysis to proton pumping for energy conversion.

/body **Introduction**

Respiratory complex I (NADH:ubiquinone oxidoreductase) (1) is a major entry point to the electron transport chain of oxidative phosphorylation in mammalian mitochondria. It catalyzes NADH oxidation coupled to ubiquinone reduction, and captures the free energy produced to transport protons (2, 3) across the mitochondrial inner membrane, supporting ATP synthesis and transport processes. Because complex I is essential for regenerating NAD^+ to sustain the tricarboxylic acid cycle and fatty acid oxidation, and an important contributor to cellular reactive oxygen species production (4), mutations in its subunits and assembly factors cause a wide range of inherited neuromuscular and metabolic diseases (5).

Mammalian complex I is a large (1 MDa) membrane-bound enzyme of 45 subunits. Due to advances in single-particle electron cryo-microscopy (cryoEM), knowledge of its structure (6–8) has surged forward recently, and descriptions of the 14 core subunits, in mammalian (6–8), fungal (9) and bacterial (10) enzymes, have laid a new foundation for mechanistic studies. NADH is oxidized by a flavin near the top of the hydrophilic domain of the L-shaped complex. Then, electrons are transferred along a chain of seven iron-sulfur (FeS) clusters to ubiquinone, bound at the interface of the hydrophilic and membrane domains. The membrane domain contains four antiporter-like units, considered to each transport one proton per cycle. They are connected by elements indicative of ion-transport activities, including π-bulges, loops in transmembrane helices (TMHs), and a series of buried charged residues, which also connects them to the quinone-binding region. Although molecular simulations have suggested how conformational, protonation, and hydration changes could propagate through the membrane domain to drive proton transfer events (11), how the energy from quinone reduction is captured and transferred to proton translocation is currently unknown. Reactions that may initiate the proton-transfer cascade include movement of a conserved aspartate upon quinone reduction (12), double reduction of Q to Q^{2-} or its subsequent protonation to QH_2 (13), and/or quinone binding/quinol dissociation. It has also been suggested that a permenantly-bound quinone shuttles between two positions in the channel, requiring an additional site for the exchangeable substrate to bind (14).

Here, we focus on ubiquinone binding and reduction by mammalian complex I. Strikingly, the binding site for the redox-active ubiquinone headgroup is ~20 Å above the membrane interface, and thought to be accessed by a long, narrow channel (Figure 1) that has been identified in all the structures described so far, but not yet confirmed experimentally.

3

The headgroup binds in a cleft between the 49 kDa and PSST subunits [we use the nomenclature for the bovine enzyme throughout] and both mutational studies in *Yarrowia lipolytica* (15) and *Escherichia coli* (16), and densities observed in structural data from *Thermus thermophilus* complex I (10), indicate that it forms hydrogen bonds with H59[49kDa] and Y108[49kDa], placing it within 12 Å of the terminal FeS cluster, N2. At the base of the cleft, the predicted channel meets subunit ND1, and runs along its interface with the 49 kDa and PSST subunits before exiting into the membrane; in total, it is long enough to accommodate most of the ~50 Å long isoprenoid tail of ubiquinone-10. Many structurally diverse inhibitors are thought to bind in the channel (17) and it is a hotspot for both pathophysiological mutations (5, 18) and site-directed variants that affect catalysis (19, 20).

Here, we have used proteoliposomes (PLs) to determine the kinetics of complex I catalysis with a series of ubiquinone substrates of varying isoprenoid tail length, from ubiquinone-1 (Q1) to ubiquinone-10 (Q10). Previous attempts to investigate the effects of quinone tail length used native membranes supplemented with exogenous quinones, following removal of the endogenous Q10 by lyophilization and pentane extraction (21–23). However, these studies were compromised because i) the quinone exchange procedures were detrimental to catalysis (the specific activities were 10-fold lower than observed here) and ii) effects on complex I activity were obscured by the catalysis of other enzymes: Lenaz et al. (23) reconstituted Q1 to Q10 into lyophilized pentane-extracted mitochondria and measured O_2 consumption, which requires complexes III and IV, whereas Estornell et al. (21) similarly reconstituted Q10 and measured cytochrome *c* reduction, which requires complex III. More recently, Fato et al. (22) assayed lyophilized pentane-extracted bovine mitochondria reconstituted with Q3, Q5 and Q10 with an NADH-Q1 reductase assay. In contrast, our PLs (24) contain highly active bovine complex I (CI, to oxidize NADH and reduce ubiquinone to ubiquinol), the cyanide-insensitive non-protonmotive alternative oxidase from *Trypanosoma brucei brucei* (AOX, to reoxidize ubiquinol to ubiquinone and reduce O_2) and varying concentrations of different ubiquinones. The system and its kinetic properties can be defined precisely through measurements of the protein, phospholipid and ubiquinone contents, and have been developed to ensure complex I is rate determining. We compare the kinetic parameters of different ubiquinones with the structural and physico-chemical properties of the quinone-binding channel to reveal new determinants of catalysis.

Results

4

Ubiquinone reduction by complex I is rate limiting for catalysis

The CI-AOX PLs described here catalyze $NADH:O_2$ oxidoreduction (the $NADH:O_2$ reaction) by redox cycling ubiquinone/ubiquinol: complex I reduces ubiquinone to ubiquinol and AOX reoxidizes it. To use the $NADH:O_2$ reaction to investigate ubiquinone reduction by complex I it must be rate limiting. Thus, the NADH (200 µM) and O_2 (200-250 µM) concentrations used are substantially higher than the K_M values of 79 ± 8 µM for complex I (measured with the $NADH:O_2$ reaction) and 10-20 µM for AOX (25). Furthermore, the k_{cat} value for NADH oxidation by the flavin in bovine complex I is >5000 s^{-1} (26), more than ten times faster than the maximum rate of NADH:ubiquinone oxidoreduction, so NADH oxidation does not limit catalysis.

The complex I and AOX used here display similar turnover rates in solution assays with ubiquinone-1, typically 250-300 s^{-1} and 200-250 s^{-1}, respectively. Thus, to increase the rate of ubiquinol oxidation, PLs were created starting from a molar ratio of 1:25 CI:AOX. The ratio then effectively doubles to $1:46 \pm 1.1$ (mean value $\pm$ S.D. for all samples) because NADH can only access complex I oriented with its active site outwards ($77 \pm 10\%$ of the total) whereas AOX substrates can access it in both orientations, and because AOX incorporates into PLs more efficiently than complex I ($80 \pm 15\%$ and $59 \pm 11\%$, respectively). This high ratio provides a strong expectation for complex I being rate limiting, and thus for the ubiquinone/ol pool being predominantly oxidized during catalysis (24). To test this expectation, titrations on the $NADH:O_2$ reaction by Q10-containing PLs with a high (1:51) or low (1:1.5) CI:AOX ratio (defined for outward facing complex I) were performed with complex I (piericidin A) and AOX (colletochlorin B (27)) specific inhibitors. For both ratios, piericidin A inhibition builds rapidly at low concentrations (Figure 2A) and the IC_{50} values are similar (2.0 ± 1.1 and 3.4 ± 1.1 nM, or 8.7 and 8.0 piericidin A per oriented complex I, respectively). In contrast, the high ratio PLs were unresponsive to low colletochlorin B concentrations (Figure 2B) and displayed an IC_{50} value 30 times greater (15.9 ± 0.03 and 0.52 ± 0.03 nM, respectively, or 0.7 and 1.4 colletochlorin B per AOX). Thus, in the high ratio (typical) preparation most of the AOX can be inhibited with little effect on catalysis, confirming that AOX is not rate limiting. High ratio PLs containing Q8, Q6, and Q4, or tested with Q2, all gave colletochlorin B IC_{50} values of 17.6 ± 1.3 nM, matching that for Q10. Only for Q1 was the IC_{50} value for colletochlorin B different; its much higher value of ~5 µM

suggests colletochlorin B is a poor inhibitor of ubiquinol-1 oxidation by AOX, or that Q1 is a poor complex I substrate.

Measurement of K_M and k_{cat} values

Figure 3 shows Michaelis-Menten curves for complex I catalyzing with Q10, Q8, Q6, Q4, Q2, and Q1. The highly hydrophobic Q10, Q8, Q6 and Q4 molecules (calculated *log*P values (cyclohexane/water) 19.4, 15.7, 12, 8.3, respectively (28)) were incorporated into the PL membranes during reconstitution so each point is from a different preparation. The samples for each curve were prepared together in batches, then their quinone, phospholipid, complex I and AOX concentrations determined. Quinone concentrations in the membrane were calculated by assuming 1 mg of phospholipid occupies ~1 µL (29), so 1 nmol of quinone per mg phospholipid is equivalent to 1 mM. The more hydrophilic Q2 and Q1 molecules were added from ethanolic stock solutions to quinone-free PLs and considered to partition between the aqueous and membrane phases. Their membrane concentrations were calculated from the phase volumes and membrane/water *log*P values, 4.0 for Q2 and 2.9 for Q1 (30). Micelle formation was not considered because the critical micelle concentration of Q2 of 14.0 µM (31) is above the maximum 10 µM concentration added, and it was confirmed that all the Q2 added could be reduced by complex I. Addition of protonophore uncouplers such as gramicidin did not increase the rate so they were not included. Finally, to account for variations in enzyme activity between the quinone-specific batch preparations, two further batches containing samples from each different quinone were prepared (see red and blue points in Figure 3); the Q1 and Q2 datasets are from quinone-free PLs included in these batches. The Q10 K_M dataset was used as the reference and scaling parameters for the other datasets derived by simultaneous non-linear least squares fitting; the scaling parameters were applied uniformly and so affect only V_{max}, not K_M.

Dependence of K_M and V_{max} on isoprenoid chain length

The K_M and V_{max} values for each ubiquinone (from Figure 3) are summarized in Figure 4. Figure 4A shows that V_{max} (or k_{cat}) is biphasic and averages to 23 ± 2 µmol min^{-1} mg^{-1} (380 s^{-1}) for Q10, Q8, Q6 and Q4, and 9.3 ± 0.9 µmol min^{-1} mg^{-1} (150 s^{-1}) for Q2 and Q1. Previous studies, using pentane-extracted mitochondria, also observed the highest NADH:O$_2$ activities from Q7 to Q10, with Q1 to Q4 only supporting ~30% of the Q10 value (22, 23). Figure 4B shows that K_M displays a bell-shaped curve with the highest value at Q4. We note that the Q10 K_M value reported here of 0.48 mM is lower than that of 3.9 mM we measured

previously (24) due to i) improvements to the AOX preparation that have increased its specific activity 2-3 fold; ii) improvements to our quinone quantification protocol; iii) the omission of alamethicin. Alamethicin was used previously (24) to open pores in the membrane to allow NADH to access all the complex I, but we have now found that 11.25 µg mL^{-1} increases the apparent Q10 K_M value from 0.5 ± 0.1 to 1.3 ± 0.4 mM. Alamethicin has been reported to sequester membrane-bound fatty acids (32) so may sequester quinones also, and to induce structural changes in the membrane (33). Finally, Figure 4C shows that the catalytic efficiency or pseudo second order rate constant, k_{cat}/K_M, increases markedly for Q8 and Q10. Previously, k_{cat}/K_M was reported to exhibit a bell-shaped dependence on substrate hydrophobicity (34) but the earlier study only used quinones with alkyl chains up to 11 carbons long, whereas the same trend is not replicated here using polyisoprenoid ubiquinones with partition coefficients that vary much more.

Analysis of structural data and docking of Q10

In order to investigate how our data correlate with structural features in complex I, we used the Caver software (35) to detect and compare the proposed quinone-binding sites in available structures. Figure S1 shows that the bovine (6), porcine (7), *T. thermophilus* (10), and *Y. lipolytica* (9) structures describe a common channel. The same channel is truncated in the ovine structure (8) by the 49 kDa subunit β1-β2 loop, and similarly constricted in the *Y. lipolytica* structure (9). Variations in the channels may arise from their medium resolutions and/or different enzyme states; both the ovine and *Y. lipolytica* enzymes were proposed to be in the 'deactive' state (8, 9) that is unable to reduce quinone, whereas the cryoEM data set for the bovine structure (6) was classified into three states and only the structure allocated to the 'active' state used here. The bovine, porcine and *T. thermophilus* channels are overlaid in Figure 1, highlighting their similarity.

To better define how quinones bind in the channel, we modeled Q10 into the channel identified in the bovine complex (PDB ID: 5LC5 (6)) and relaxed the system by atomistic molecular dynamics (MD) simulations (Figure 5A). Subsequently, by truncating the relaxed Q10 model, we performed further MD simulations for Q8, Q6, Q4, Q2, and Q1 (Figure 5B). Analyses of the Q10-bound structure showed that its channel closely matches the original channel (Figure S1) and, in all cases, the modeled protein structures around the bound quinones remain in similar conformations except that, for Q1 to Q6 and the empty site, the sidechain of F224^{ND1} moves into the position of isoprenoid-7 (Figure S2A). Notably, the root-mean-square fluctuations (RMSFs) of the bound quinone variants suggest that the long

isoprenoid chains of Q8 and Q6, which overlay closely on that of Q10 (Figure 5B), are spatially tightly constrained by the channel, whereas the shorter chains of Q4, Q2 and Q1 have much greater conformational freedom (Figure 5C).

Strikingly, Figure 6 shows how the properties of residues close to the modeled Q10 vary along it (Figure S3 presents equivalent data for Q8 to Q1). The environment of the headgroup plus isoprenoids 1 to 3, in the cleft between the PSST and 49 kDa subunits, is primarily hydrophobic and uncharged. Conversely, that of isoprenoids 4 to 7 contains many charged residues. In particular, a group of highly conserved arginines (Figure 5A) form an channel elbow that produces a ~100° kink in the modeled Q10 between isoprenoids 4 and 5. Notably, the hydrophobic faces of the Arg guanidiniums form π-stacking interactions with the isoprenoids, while their edges form polar and electrostatic interactions with a set of conserved Glu/Asp residues (Figure 5A), consistent with the known behavior of guanidium groups (36). In the modeled structures, interactions between the charged residues separate them into two groups (Figure S2B), with the group involving residues on ND1 TMH1 showing less positional variation than that involving primarily residues on the ND1 TMH5-6 loop (Figure S2C), noted previously for its flexibility (6). Finally, for isoprenoids 8 and 9 the expected hydrophobic nature of the ubiquinone-binding channel is re-established.

Discussion

Entry and exit of quinone/quinol to and from the channel

In the classical Michaelis-Menten model, k_{cat} encapsulates all the steps that follow formation of the enzyme-substrate complex, so the fact that k_{cat} is constant for Q4 to Q10 (Figure 4A) suggests that product dissociation, which is expected to be chain-length dependent, is not rate limiting. Alternative rate-limiting steps include the electron-proton transfers for quinone reduction, the coupled processes leading to proton translocation, and all the reactions required to complete the catalytic cycle.

For Q2 and Q1, k_{cat} (150 s^{-1}) is substantially lower than for Q4 to Q10 (380 s^{-1}) (Figure 4A) so the rate-limiting step has either slowed or changed identity. Both possibilities indicate that a chain-length dependent step, such as product dissociation, has slowed down. Furthermore, the pseudo second-order rate constant k_{cat}/K_M (where $K_M = (k_{off} + k_{cat})/k_{on}$) provides a guide to the rate constant for substrate binding (k_{on}) since it approximates to it when $k_{cat} > k_{off}$ and reflects how fast the rate increases with increasing concentration, in

substrate-limiting conditions. k_{cat}/K_M increases substantially with isoprenoid-tail length (Figure 4C). Both observations are consistent with rates of binding and dissociation (*i.e.* channel transit rates) increasing with isoprenoid chain length, and being limiting only for Q2 and Q1. We propose three explanations. First, the short isoprenoid tails of Q1, Q2 and Q4 do not overlay their respective Q10 isoprenoids (Figure 5B) so they are conformationally mobile within the site (Figure 5C): their dissociation may be hindered by lack of directionality, due to lack of a guiding anchor extending down the channel. The tail of Q10 extends into the membrane and may guide the entire dissociation process. Second, for the shorter quinones an additional molecule(s) may enter the channel behind the substrate, impeding its dissociation. Third, the channel entrance is at a similar depth below the membrane interface to the favored position for the ubiquinone-10 headgroup (37), whereas shorter-tail quinones may distribute differently in the membrane, affecting their binding rates.

Finally, while the simple Michaelis-Menten mechanism provides a convenient framework for interpreting our data, it does not account for the unusual nature of the ubiquinone-binding channel in complex I. Transfer along the whole channel is unlikely to occur over a single transition state but over a complex energy surface that may form local minima and transient binding sites. Longer chains species may move faster along the channel because their stepwise movements incur minimal changes. For example, moving a Q10 molecule by one step requires only the residues (and water molecules) around the headgroup and the leading isoprenoid to reorganize (at all other positions one isoprenoid simply replaces another), whereas moving a short chain quinone reguires the region behind it to reorganize also. The energy surface for Q10 transit along the channel may therefore be flatter. In this way, the unusually long substrate-binding channel in complex I need not exert a rate limiting effect on catalysis.

Effect of isoprenoid chain length on binding affinity

In classical Michaelis-Menten kinetics, K_M is expressed as $(k_{off} + k_{cat})/k_{on}$ so, for Q4 to Q10, where k_{cat} is constant (Figure 4A) but K_M decreases with increasing chain length (Figure 4B), k_{off} decreases and/or k_{on} increases. Both possibilities suggest that K_d (= k_{off}/k_{on}) decreases, such that Q4 binds most weakly and Q6, Q8 and Q10 progressively more tightly. The comparison does not extend to Q2 and Q1 because k_{cat} is different, but as their k_{cat} values are similar the same considerations suggest Q1 binds more tightly than Q2. Thus, although a robust comparison between Q4 and Q2 is currently not possible, we may infer that the curve describing K_d qualitatively resembles that of K_M.

The relative free energy changes that result from moving each quinone species from a low dielectric (membrane) environment into its complex I binding site were evaluated using continuum electrostatics calculations (38), revealing a linear dependence on isoprenoid number (Figure S4). The trend is consistent with the decreasing K_d proposed for Q4 to Q10, but not with the decrease proposed for Q4 to Q1. Intriguingly, the discrepancy can be explained by considering that k_{off} for Q4, Q2 and Q1 may be decreased, as discussed above, by them lacking a guiding chain for dissociation, and by additional substrate molecules blocking their exit. By decreasing k_{off} these factors 'cage' short chain species in the binding site, independently of their intrinsic affinity for it, and decrease K_d. Notably, many tight-binding hydrophobic complex I inhibitors match the dimensions of Q1 to Q4 and are considered to occupy the same binding site; density attributed to piericidin A, which resembles Q3, was observed to overlay density attributed to decylubiquinone in crystallographic maps from *T. thermophilus* complex I (10). Thus, the potent inhibition of these molecules may also partly result from caging effects.

The concept of a highly-charged channel for the hydrophobic isoprenoid chain, as observed for isoprenoids 4 to 7 (Figures 5 and 6), is intrinsically challenging. Charged cavities in proteins tend to fill with water molecules (39), and indeed, in MD simulations on the structure of *T. thermophilus* complex I, waters accumulate in the channel, especially in the charged region (11). If waters are present it may be that i) the channel has become hydrated artificially during the extended handling required for structural work, or ii) during every catalytic cycle the quinone displaces waters, making an entropic contribution to offset the enthalpy loss of breaking charged and polar interactions. In fact, an unfavourable binding enthalpy from the charged region may mitigate the increasing affinity due to binding an increasing number of hydrophobic units within a hydrophobic channel, and be important for efficient product release. Higher resolution structural data is required for further understanding of this intriguing structural feature.

Finally, increased contributions to the binding affinity from the second, non-polar region at isoprenoids 8 and 9 causes a marked increase in k_{cat}/K_M (Figure 4C). Because k_{cat} is constant from Q4 to Q10, k_{cat}/K_M is dominated by the reciprocal of K_M and the apparent discontinuity in Figure 4C results simply from a point of inflexion in the K_M curve.

How is proton translocation coupled to quinone reduction?

The identity of the coupling point, at which the redox reaction initiates proton translocation, is currently the most important unknown feature of the complex I mechanism. Molecular

dynamics simulations of the movement of D160^{49kDa} away from H59^{49kDa}, as a result of proton transfer from H59 to the nascent quinol, have been used to illustrate one possibility (12). Alternatively, could conformational changes triggered by quinone/quinol moving along the channel, particularly through the charged section, trigger proton translocation? If so, short chain quinones must activate the mechanism as effectively as long chain quinones, since they elicit the same proton-pumping stoichiometry (2, 3). As Figure 5A shows, the charged residues surrounding the channel are, like D160, connected to the center of the membrane domain by a chain of acidic residues (6–10, 12) suggesting how quinone/ol binding/dissociation may be communicated to the proton translocation machinery. To elucidate, challenge and add to proposals for the mechanistic coupling point in complex I requires higher resolution structures set in different states, alongside mutational, functional and computational studies to provide complementary strategies and perspectives on tackling this difficult problem.

Experimental methods

Preparation of AOX

The construct described previously for over-expression of AOX from *T. brucei brucei* (40) was modified by removing the *N*-terminal mitochondrial targeting peptide (residues 1-24) and replacing the 6xHis tag with a Twin-Strep® tag (IBA GmbH) (41). The modified AOX was over-expressed in *E. coli* strain FN102 (40) in a 60 L fermenter as described previously (24, 40), except using 100 µg mL^{-1} ampicillin instead of carbenicillin. The culture was incubated at 30 °C, 60% O$_2$ saturation until OD$_{600}$ ~0.6, then expression induced with 25 µM isopropyl β-D-1-thiogalactopyranoside for 12 hours. Cells (200-300 g) were collected by centrifugation then membranes prepared immediately (24) and resuspended to ~30 mg protein mL^{-1} in 50 mM Tris-HCl (pH 8.0 at 4 °C) for storage at -80 °C.

All the following steps were at 4 °C. 20 mL of membranes were solubilized at 6 mg protein mL^{-1} in 25 mM Tris-HCl (pH 8.0 at 4 °C), 200 mM MgSO$_4$, 1.4% (w/v) n-octyl-glucopyranoside (Anagrade, Anatrace) and 20% (v/v) glycerol for 1 hour then centrifuged (165,000 x *g,* 30 min.). The supernatant was loaded onto a ~8 mL column of Strep-Tactin® Superflow® high capacity resin (IBA GmbH) pre-equilibrated in Strep buffer: 20 mM Tris-HCl (pH 8.0 at 4 °C), 50 mM MgSO$_4$, 160 mM NaCl and 20% (v/v) glycerol (41). AOX was eluted in Strep buffer supplemented with 2.5 mM desthiobiotin (Sigma Aldrich) and 0.042%

n-dodecyl-β-D-maltopyranoside (DDM) (Anagrade, Anatrace) (41). Pooled AOX-containing fractions were concentrated ten-fold, then dialyzed for 6 hours against 2 L of Strep buffer plus 0.042% DDM (24). Typical preparations yielded 3-5 mg AOX and were ≥95% pure by SDS-PAGE.

Preparation of complex I

Mitochondrial membranes were prepared from *Bos taurus* (bovine) heart (42) then complex I prepared as described previously (24), with minor modifications. Membranes were solubilized at 5 mg mL^{-1} protein in 1% DDM. The Q-sepharose buffers consisted of 20 mM Tris-HCl (pH 7.55 at 4 °C), 2 mM EDTA, 10% (v/v) ethylene glycol, 0.2% (w/v) DDM, 0.02% asolectin (total soy lipid extract, Avanti Polar Lipids) and 0.02% 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS). Size exclusion chromatography was conducted on a Superose™ 6 Increase 10/300 column (GE Healthcare) in 20 mM Tris-HCl (pH 7.55 at 4 °C), 200 mM NaCl, 0.05% DDM and 10% (v/v) glycerol. Samples were flash frozen for storage at ~20 mg mL^{-1} in 30% (v/v) glycerol.

Preparation of CI-AOX PLs

Chloroform solutions (25 mg mL^{-1}) of bovine heart phosphatidylcholine (PC), phosphatidylethanolamine (PE) and cardiolipin (CL) were from Avanti Polar Lipids. Chloroform stock solutions of Q10 (Sigma Aldrich), Q8 (Avanti Polar Lipids), Q6 (Avanti Polar Lipids) and Q4 (Santa Cruz Biotechnology) were created at 2-4 mM. PLs were prepared as described previously (24), starting from mixtures of 8 mg PC, 1 mg PE, 1 mg CL and quinone (as required).

Characterization of PLs

To quanitify the quinone present, 90 µL of ethanol (HPLC grade Chromasolv, Sigma Aldrich) was added to 10 µL of PL solution, sonicated (1 min.) and centrifuged (16,300 x *g*, 10 min.). 50 µL of supernatant were injected onto a Nucleosil 100-5C18 (Hichrom) column, and run at 30 °C at 800 µL min^{-1} on an Agilent 1100 series HPLC in 70% ethanol, 30% methanol, 0.07% HClO$_4$ and 50 mM NaClO$_4$ for Q10 and Q8, or in 100% methanol, 0.07% HClO$_4$ and 50 mM NaClO$_4$ for Q6 and Q4 (retention times 9, 6, 10 and 5 min., respectively). Concentrations were determined by comparison with known standards. Total phospholipid content was determined as detailed previously (24). Total protein contents were quantified by the amido black assay, which is insensitive to detergents and high phospholipid

concentrations (43). The NADH:APAD[+] oxidoreduction assay was used to determine the total complex I content and orientation together with 15 µg mL[-1] alamethicin to allow NADH into the PL lumen (24). The AOX content was taken as the difference between the total protein and complex I contents.

Catalytic activity assays

Activity assays were at 32 °C in 10 mM Tris-SO$_4$ (pH 7.5 at 32 °C), 50 mM KCl, 200 µM NADH with ~1.5 mg protein mL[-1] PLs (24). NADH oxidation was monitored at 340-380 nm (ε = 4.81 mM[-1] cm[-1]) on a Molecular Devices Spectramax 384 plus platereader. Q2 and Q1 (Sigma Aldrich) were added in ethanol. Inhibitor-insensitive rates were determined in 0.5 µM piericidin A as 0.30 ± 0.03 µmol NADH min[-1] mg CI[-1] for all quinones except Q1 (which exhibited a concentration-dependent inhibitor-insensitive rate) and have been subtracted from the data reported.

Molecular modeling of ubiquinone-bound structures

Ubiquinone-10 was docked into a channel identified by the HOLE software (44) in the structure of bovine complex I (PDB ID: 5LC5) with missing amino acid side chains modelled in (6). Then, 20 ns of classical molecular dynamics (MD) simulation (integration time step 2 fs, 310 K) were performed using NAMD2 (45) with the CHARMM36 force field (46), and DFT-derived parameters for all cofactors (12). Backbone atoms of the 49 kDa, ND1, and PSST subunits were harmonically restrained (force constant 2 kcal mol[-1] Å[-2]), with positional constraints for all other subunits. The A57-V61 and L106-S110 loops of the 49 kDa subunit that carry H59 and Y108 were not restrained. For the Q1-Q8 bound structures, the Q10 molecule was truncated and each variant relaxed for a further 10 ns. Free energies for quinone solvation into complex I were estimated by the MM-GBSA method (38), using 50 snapshots extracted from 10 ns MD simulations. The modeled structures with Q1 to Q10 bound and with the empty site are available from the University of Cambridge data repository (https://doi.org/10.xxxxx/CAM.xxxxx).

Figure Legends

1. The proposed ubiquinone-binding channel in mammalian complex I. The 49 kDa, PSST and ND1 subunits from bovine complex I (5LC5.pdb (6)) are in cartoon, with the surfaces of predicted quinone-binding cavities in the aligned structures of the bovine (6) (cyan), porcine (7) (yellow) and *T. thermophilus* (10) (purple) enzymes. The quinone headgroup is considered to hydrogen bond to Y108 and H59, and H59 to D160. The carboxylate groups of acidic residues connecting the quinone-binding region to the proton pumping subunits are shown by red spheres. Cavities were generated using the Caver 3.0 PyMOL plugin (35) with a 1.4 Å probe.
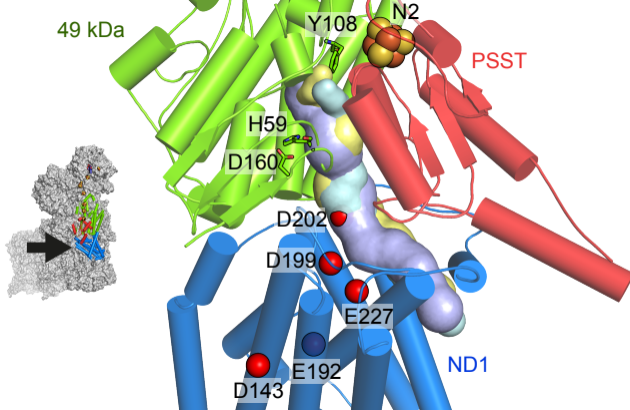

2. Complex I is rate limiting for catalysis in CI-AOX PLs. Normalized rates of the NADH:O_2 reaction by PLs containing high (1:51, blue) and low (1:1.5, red) ratios of oriented-CI:AOX are shown. Both preparations contained ~10 mM Q10. A) Inhibition by piericidin A. B) Inhibition by colletochlorin B.
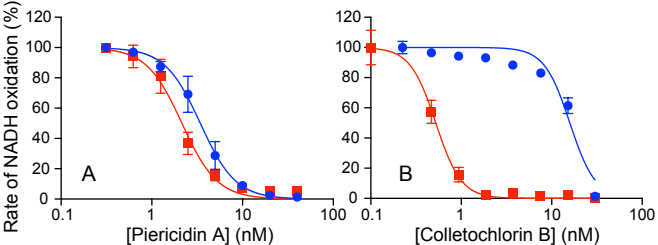

3. Michaelis-Menten curves for reduction of Q1 to Q10 by complex I. The black points are from sets of PLs with different quinone concentrations; the datasets for Q1 to Q8 were adjusted to the Q10 dataset using the red and blue datasets and scaling factors of 1.44 (Q8), 1.35 (Q6), 1.86 (Q4), 1.57 (red points), 1.60 (blue points). Each value is the mean of at least three replicates ± the standard deviation propagated from each underlying measurement.
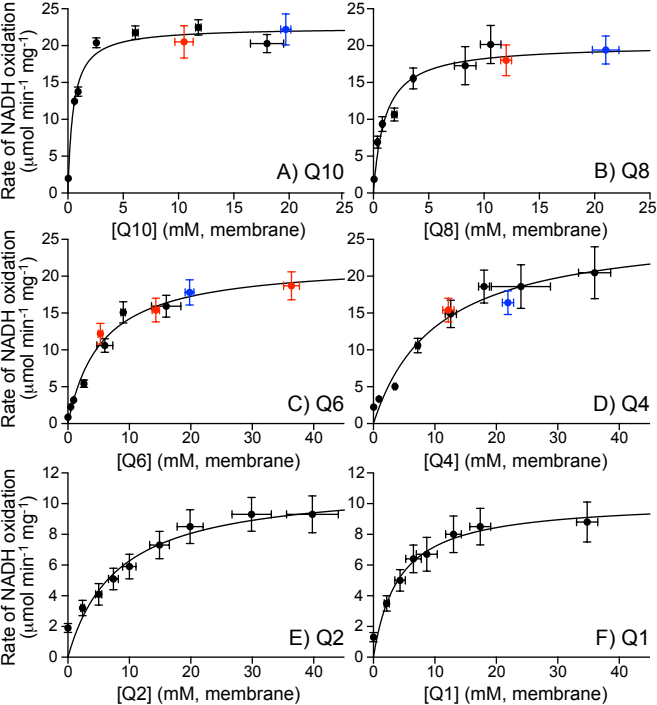

4. Dependence of the Michaelis-Menten parameters on isoprenoid chain length. (A) V_{max} and k_{cat} values shown with average values of 9.3 ± 0.9 µmol min^{-1} mg^{-1} (150 ± 15 s^{-1}) for Q1 to Q2 and 23 ± 2 µmol min^{-1} mg^{-1} (380 ± 39 s^{-1}) for Q4 to Q10. (B) K_M values; the curve is only to guide the eye. (C) k_{cat}/K_M values with two linear fits (gradients 7.0 and 220 mM^{-1} s^{-1} isoprenoid unit^{-1}). Values are from the data in Figure 3 and also given in Table S1.
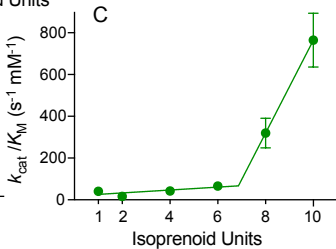

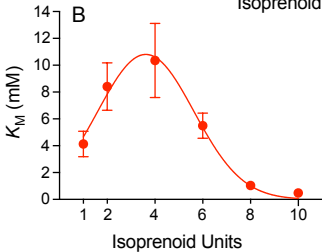

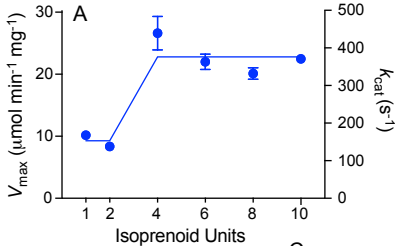

5. Modeled structures of bovine complex I with Q1 to Q10 bound. A) The modeled Q10 molecule with its isoprenoids in black and cyan alternately, alongside the sidechains of charged residues within 5 Å (red, PSST; blue, ND1). Green: 49 kDa subunit residues hydrogen bonded to the ubiquinone headgroup. B) The overlaid modelled structures for Q10, Q8, Q6 and Q4, and (inset) for Q10, Q4, Q2 and Q1. C) RMSFs for each quinone species from MD simulations, colored as in B.
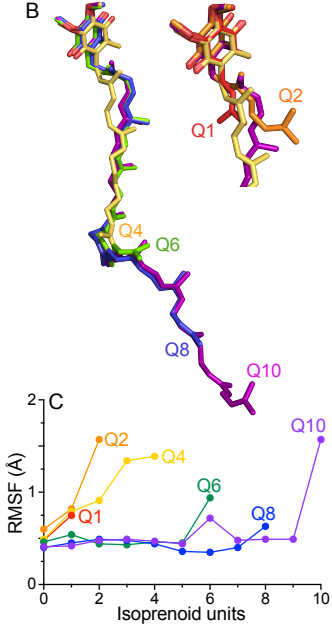

6. The protein environment of the modeled bound Q10 molecule in the structure of bovine CI. A) Percentage of residues within 5 Å of each isoprenoid that are hydrophobic (A, F, I, L, M, P, V, W, Y) or hydrophilic (C, D, E, G, H, K, N, Q, R, S, T). B) Percentage of residues within 5 Å of each isoprenoid that are canonically charged (D, E, H, K, R), and that are arginines.

S1. Predicted quinone-binding cavities in published complex I structures. A) The active state of bovine complex I (PDB ID: 5LC5) (6). B) The bovine structure with Q10 modeled in using MD simulations (Q10 was removed for the channel prediction). C) Complex I from the porcine respirasome (PDB ID: 5GUP) (7). D) *T. thermophilus* complex I (PDB ID: 4HEA) (10). (E) *Y. lipolytica* complex I (PDB ID: 4WZ7) (9). F) Ovine complex I (PDB ID: 5LNK) (8) in which the cavity is blocked by the β1-β2[49kDa] loop; the cavity from panel A is overlaid as a mesh for comparison. G) The active state of bovine complex I (PDB ID: 5LC5) with the modeled Q10 structure overlaid. H) The bovine structure with Q10 modeled in using MD simulations. Cluster N2 is shown as spheres and Y108[49kDa] is shown because its hydroxyl oxygen was used as the starting point for cavity searches. Channels were predicted using the Caver 3.0 plugin in PyMOL (35) with a probe size of 1.4 Å or 1.1 Å for panel E.

S2. Conformational changes in the modeled ubiquinone-bound states. A) The sidechain of F224[ND1] responds to the isoprenoid chain in energy-minimized structures with different species bound. For Q1 to Q6 and the ubiquinone-free state, it obstructs the channel at isoprenoid 7, whereas for Q8 and Q10 it has moved away. Also shown are variations in the positions of the sidechains of Y108 and H59 in the presence and absence of the ubiquinone headgroup. B) The charged residues within 5 Å of isoprenoids 4 to 7 form two distinct groups of interacting residues. Predicted hydrogen bonds are shown with dashed yellow lines. C) The sidechains in the right-hand set (including residues on a nearby helix) show less variation in their positions between the different states than those in the left-hand set that are predominantly present on loops.

S3. Comparison of the protein environments of quinone molecules with different isoprenoid chain lengths in modeled structures. A) The percentage of residues within 5 Å of each isoprenoid unit that are classified as hydrophobic (A, F, I, L, M, P, V, W, Y). B). The percentage of residues within 5 Å of each isoprenoid unit that are classified as hydrophilic (C, D, E, G, H, K, N, Q, R, S, T). C) The percentage of residues within 5 Å of each isoprenoid unit that are canonically charged (D, E, H, K, R). D) The percentage of residues within 5 Å of each isoprenoid unit that are arginine.

S4. Estimated relative free energies for solvation of quinone in the complex I binding site for each quinone variant. The free energies of solvation were estimated using continuum electrostatics calculations on 50 snapshots extracted from the MD simulations, by the MM-

GBSA method (38). The calculation provides a free energy change relative to quinone in a reference medium, here the low dielectric membrane slab. All values are given relative to the value for Q1. Although this simplified MM-GBSA model accounts for electrostatic solvation free energies, it does not account for entropic contributions. A complete treatment would require computationally-demanding free energy calculations that are not currently justified by the resolution of available structural data.
